Abstract. Statistical physics approaches can be used to derive accurate predictions for the performance of inference methods learning from potentially noisy data, as quantified by the learning curve giving average error versus number of training examples. We analyse a challenging problem in the area of non-parametric inference where an effectively infinite number of parameters has to be learned, specifically Gaussian process regression. When the inputs are vertices on a random graph and the outputs the noisy function values being fitted, we show that replica techniques can be used to obtain exact predictions in the limit of large graphs. The covariance of the Gaussian process prior is defined by a random walk kernel, the discrete analogue of squared exponential kernels on continuous spaces. Conventionally this kernel is normalised only globally, so that the prior variance can differ between vertices; as a more principled alternative we consider local normalisation, where the prior variance is uniform. The starting point is to represent the average error as the derivative of an appropriate partition function. We rewrite this in terms of a graphical model, where only neighbour vertices are directly coupled. Treating the average over training examples and random graphs in a replica approach then yields learning curve predictions for the globally normalised kernel. The results apply generically to all random graph ensembles constrained by a fixed but arbitrary degree distribution. For the locally normalised kernel, the normalisation constants for the prior have to be defined as thermal averages in an unnormalised model. This case is therefore technically more difficult and requires the introduction of a second auxiliary set of replicas. We compare our predictions with numerically simulated learning curves for two paradigmatic graph ensembles: Erdős-Rényi graphs with a Poisson degree distribution, and an ensemble with a power law degree distribution. We find excellent agreement between our predictions and numerical simulations. We also compare our predictions to existing learning curve approximations. These show significant deviations; we analyse briefly where these arise.

1. Introduction

Ever since the seminal work of Seung, Sompolinsky and Tishby [1], it has been recognised that statistical physics can make significant contributions to the understanding of methods and algorithms that learn from examples. The performance of a learning algorithm or inference method is captured in the *learning curve*, which records the average prediction error over all training sets of a given size, or *generalisation error*, as a function of the number of training examples.

Learning curves have been successfully analysed using statistical physics for a variety of parametric learning methods (where a finite number of parameters must be learned) by taking advantage of the interpretation of the average over training sets as quenched disorder [1, 2, 3, 4, 5, 6]. Rather more challenging is the non-parametric case, where the number of parameters is effectively infinite. An important example in this class is the learning of functions (regression) with *Gaussian process (GP)* priors. Here the set of parameters to be learned is in essence the entire underlying function that one is trying to estimate from the data. GPs have been widely adopted in the machine learning community as efficient and flexible inference methods. This is due to a few important advantages, namely that prior assumptions about the function to be learnt can be seamlessly encoded in a transparent way, and that inference (at least in the case considered in this paper) is relatively straightforward.

The general regression setting is as follows. We are given a set of data $(\mathbf{x}, \mathbf{y})$ consisting of a set of inputs $\mathbf{x} = (x_1, \dots, x_N)^T$ and a corresponding vector of outputs $\mathbf{y} = (y_1, \dots, y_N)^T$ and wish to infer the underlying true function $y = f(x)$. In a Bayesian approach we infer not a single function f , but a posterior distribution, $P(f|\mathbf{x}, \mathbf{y})$, over a function space. The posterior distribution is calculated from two elements: a likelihood $P(\mathbf{y}|f, \mathbf{x})$ which measures the probability the outputs $\mathbf{y}$ were generated by a particular function f , and a prior distribution $P(f)$ which encodes any prior beliefs about how plausible different functions would be in the absence of data. The prior can encode properties such as the expected smoothness of the function, its typical amplitude, or the lengthscale on which it varies across the input space. The posterior is calculated from the prior and likelihood using Bayes' theorem:

$$P(f|\mathbf{x}, \mathbf{y}) = \frac{P(\mathbf{y}|f, \mathbf{x})P(f)}{\int df' P(\mathbf{y}|f', \mathbf{x})P(f')}. \quad (1)$$

For the particular case of GPs, the prior is assumed to be a Gaussian process [7]. This means that any set of function values $f(x_1), \dots, f(x_k)$ is assumed to have a joint Gaussian distribution. The statistics of this Gaussian distribution, and hence the Gaussian process, are specified by a *covariance function* or *kernel* $C(x, x')$ and a *mean function*, $\mu(x)$. The kernel gives the covariance $\langle f(x)f(x') \rangle$ under the prior between the values of f at input points x and x' . It is the kernel that gives GPs and other kernel based methods their intuitive nature as it describes in a simple manner prior assumptions such as smoothness, lengthscale of variation and typical amplitude of the function we aim to learn. The mean function $\mu(x)$ gives the average of $f(x)$ under the

prior, and is normally set to zero unless one has very strong prior knowledge about a non-zero function mean.

We will consider the simplest case for the likelihood: that data points y_μ are generated by corrupting $f(x_\mu)$ with normally distributed noise, i.e. $P(\mathbf{y}|f, \mathbf{x}) \propto \exp(-\sum_\mu (f(x_\mu) - y_\mu)^2)/(2\sigma^2)$. Then the posterior distribution is again a Gaussian process, and the posterior mean and variance of $f(x)$ can be expressed in closed form as [7]

$$\bar{f}(x^*) = \mathbf{k}(x^*)^\top \mathbf{K}^{-1} \mathbf{y} \quad (2)$$

$$\text{Var}(f(x^*)) = C(x^*, x^*) - \mathbf{k}(x^*)^\top \mathbf{K}^{-1} \mathbf{k}(x^*) \quad (3)$$

with the matrix $\mathbf{K}$ and vector $\mathbf{k}$ having entries $K_{ij} = C(x_i, x_j) + \delta_{ij}\sigma^2$ and $k_i(x^*) = C(x_i, x^*)$ respectively. One would then use $\bar{f}(x^*)$ as the prediction for the function value at a test input x^* , and the square root of the posterior variance can be used to give an error bar for this prediction.

Analysing the average performance of GPs at predicting a function from data, i.e. calculating the learning curve, is an interesting problem that has been well studied for the case of functions defined over continuous spaces [8, 9, 10, 11, 12, 13, 14, 15]. However, far less is understood about the learning curves for GP regression for functions defined on discrete spaces. With the rise of large structured data such as the internet, author collaboration networks, protein networks and financial markets, such an understanding of the performance of GPs, and machine learning techniques in general, on discrete spaces is becoming important.

In this paper we concern ourselves with obtaining predictions for the learning curves of GP regression for functions on large random graphs. We study GPs trying to predict a function $f : \mathcal{V} \rightarrow \mathbb{R}$ defined on the vertices of a graph $G(\mathcal{V}, \mathcal{E})$ with vertex set $\mathcal{V}$ and edge set $\mathcal{E}$. As is standard in the analysis of GP learning curves we will focus on GPs with zero mean. (Our results can easily be generalised to non-zero mean, but at the expense of increased notational complexity which we avoid here.) We note that in the context of GPs on graphs the covariance function will be a $V \times V$ covariance matrix where $V = |\mathcal{V}|$ is the number of vertices of the graph.

We focus on GPs with covariance structure described by a *random walk kernel* first introduced in [16] and further developed in [17]. These are generalisations of the frequently used square exponential kernels in continuous spaces (see for example [7]). We define the random walk kernel by:

$$\begin{aligned} \mathbf{C} &= \mathbf{K}^{-1/2} (\mathbf{I} - a\mathbf{L})^p \mathbf{K}^{-1/2} \\ &= \mathbf{K}^{-1/2} \left((1 - a^{-1})\mathbf{I} + a^{-1}\mathbf{D}^{-1/2}\mathbf{A}\mathbf{D}^{-1/2} \right)^p \mathbf{K}^{-1/2}, \end{aligned} \quad (4)$$

where a and p are hyperparameters of the kernel, $\mathbf{K} = \text{diag}(\kappa_1, \dots, \kappa_V)$ is a normaliser which controls the prior variance of f , $\mathbf{I}$ is the identity matrix, $\mathbf{A}$ the adjacency matrix of G ($a_{ij} = 1$ if $(i, j) \in \mathcal{E}$, $a_{ij} = 0$ otherwise), $\mathbf{D}$ is the diagonal degree matrix with $D_{ii} = \sum_j a_{ij}$ and $\mathbf{L} = \mathbf{I} - \mathbf{D}^{-1/2}\mathbf{A}\mathbf{D}^{-1/2}$ the normalised Laplacian [18]. (The Laplacian defined in [18] differs slightly, in that for single vertices i that are disconnected from

the rest of the graph it has $L_{ii} = 0$. Our definition has $L_{ii} = 1$ for this case, which we presume to be consistent with the usage in [16, 17]. In the case of graphs without single disconnected vertices the two definitions of the normalised Laplacian will agree. We use this adjusted normalised Laplacian because analysis is easier without the special case and for local normalisation of the kernel, for which we will shortly argue in favour of, the resulting normalised covariance function will be the same.) Equation (4) is called the random walk kernel because it defines the importance of neighbouring vertices in predicting a function value at some given vertex i in terms of the frequency with which a lazy random walk starting from i lands at the neighbour. We can view a^{-1} as the probability of making a ‘step’ and p the number of attempts the walker makes. With this interpretation p/a , the average number of steps of the lazy random walk, can be thought of as the lengthscale of (4) [19].

We will consider two normalisations of the random walk kernel: *global normalisation* and *local normalisation*. In the case of global normalisation we fix all κ_i to be equal, chosen such that the average prior variance $(1/N) \sum_{i=1}^V C_{ii}$ has the desired value which we fix to unity. For local normalisation, we set the κ_i so that the function value at each vertex has the same prior variance, namely $C_{ii} = 1$. It is worth noting, that from a Bayesian modelling point of view, local normalisation is more natural since we do not expect to have strong prior knowledge that would justify using different prior variances at different vertices. However, we also analyse the case of global normalisation because that is the form for the kernel suggested in [16, 17] and used in e.g. [20, 21, 22]. This case also serves to illustrate the general structure of the replica approach we use for the analysis, before we tackle the rather more challenging scenario of local normalisation.

Our main aim in this paper is to show that for the setting of GP regression of functions on graphs we can calculate the learning curve exactly in the limit of large graphs. Our results will be valid for graphs chosen from a broad range of random graph ensembles, which are defined by an arbitrary degree distribution. This is rather remarkable: in the case of GP regression of functions defined on continuous spaces, exact learning curve predictions are possible only in very special cases [23]. Otherwise, one has to rely on approximations that typically give only qualitatively accurate predictions, and can fail dramatically in some scenarios, e.g. for low noise level σ^2 .

The rest of this paper is structured as follows: we begin in section 2 by defining the generalisation error and expressing it in terms of a generating partition function. This is then rewritten in a form that can act as a suitable starting point for a replica approach, using additional variables to obtain a model with interactions only between neighbouring vertices. We briefly compare our method to a similar approach by Oppen [24] and point out when our method and that of Oppen’s diverge. In section 3 we use a replica approach to calculate the learning curves. We show in section 3.1 that the case of global normalisation can be solved by applying a method similar to that used in [25]. In section 3.2 we proceed to analysing learning curves for the locally normalised kernel. We show that the introduction of local normalisation brings a great deal more complexity to the problem: we need to use an additional set of replicas to account for the fact that

the normalisation is now tied tightly but in a non-local way to the quenched disorder given by the graph structure. The statistics of the auxiliary replicas are obtained by a saddle point approach that is nested inside the conventional saddle point method for the ordinary replicas. Section 4 compares our replica predictions to numerically simulated learning curves and existing learning curve approximations [8, 24], suitably extended from continuous to discrete input spaces. We also discuss the qualitative differences between the learning curves produced by the globally and locally normalised kernels. Finally section 5 summarises our results and discusses potential avenues for future research.

2. Learning curves

To begin with we express the generalisation error for GP regression on a large random graph as the derivative of an appropriate partition function Z . We will introduce additional variables to get this into the form of an *undirected graphical model*. By this we mean, following the terminology in the machine learning literature, a Boltzmann distribution with a Hamiltonian containing, in addition to local “energy” contributions for each vertex, only pairwise interaction energies between neighbouring vertices on the graph. By making some assumptions on the graph structure, namely that the graph is random subject to an arbitrary specified degree distribution, we will be able to apply a replica method to calculate the dependence of the generalisation error on the number of training examples, i.e. the learning curve. Physically, the reason that this procedure can be carried through is the fact that random graphs from the ensembles considered here typically have locally tree-like structures. Accordingly, the results that we find can also be derived using a cavity method [26, 27].

The generalisation error of a GP is defined as the squared deviation between the predicted function, i.e. the student’s posterior mean, $\langle \mathbf{f} \rangle_{\mathbf{f}|\mathbf{x},\mathbf{y}}$, and the true teacher function $\mathbf{g}$ that generated the data. This is then averaged over data sets, i.e. noise corrupted outputs y_μ generated from the true function $\mathbf{g}$ for a fixed set of inputs $\mathbf{x}$, and independently and identically distributed inputs x_μ . Finally one averages over the prior distribution of teachers $\mathbf{g}$ (in this paper assumed to be a GP) and, in our random graph setting, the graph ensemble $\mathcal{G}$:

$$\epsilon_g = \left\langle \left\langle \left\langle \left\langle \frac{1}{V} \sum_{i=1}^V (g_i - \langle f_i \rangle_{\mathbf{f}|\mathbf{x},\mathbf{y}})^2 \right\rangle_{\mathbf{y}|\mathbf{g},\mathbf{x}} \right\rangle_{\mathbf{x}} \right\rangle_{\mathbf{g}} \right\rangle_{\mathcal{G}}. \quad (5)$$

Here we have defined $\mathbf{f}$ and $\mathbf{g}$ to be V -dimensional vectors with $f_i = f(x_i)$ and $g_i = g(x_i)$.

In this paper we will assume, as is typical (though see [23]) in learning curve calculations, that teacher and student have the same posterior distribution, i.e. a *matched scenario*. The generalisation error in this case is also the Bayes error, i.e. the lowest average error achievable for a teacher function from the given GP prior. Under this assumption (5) simplifies to just the posterior variance of the student (see

for example [7]). Since we require only the posterior variance we shift our functions so that f_i now represents the deviation of the function $\mathbf{f}$ from the posterior mean. The generalisation error can then be expressed as

$$\epsilon_g = \left\langle \left\langle \left\langle \frac{1}{V} \sum_{i=1}^V f_i^2 \right\rangle_{\mathbf{f}|\mathbf{x}} \right\rangle_{\mathbf{x}} \right\rangle_{\mathcal{G}}. \quad (6)$$

The posterior for the redefined $\mathbf{f}$ is proportional to the product of the prior $P(\mathbf{f})$ and the quadratic exponential terms from the likelihood $P(\mathbf{y}|\mathbf{f}, \mathbf{x})$. The latter are $\exp(-\sum_{\mu} f_{\mu}^2/(2\sigma^2)) = \exp(-\sum_{i=1}^V \gamma_i f_i^2/(2\sigma^2))$ where γ_i counts the number of examples seen at vertex i . Note that in line with the expression (3) for the GP variance not depending on the training outputs, the posterior distribution for the shifted function values only depends on the training inputs, hence the notation $f|\mathbf{x}$ rather than $f|\mathbf{x}, \mathbf{y}$ in (6). For the same reason we have also been able to drop the averages over $\mathbf{y}$ and $\mathbf{g}$.

We now wish to rewrite (6) in terms of a graphical model. Taking a statistical physics approach we rewrite the generalisation error in terms of a generating partition function Z :

$$\epsilon_g = -\frac{2}{V} \lim_{\lambda \rightarrow 0} \frac{\partial}{\partial \lambda} \langle \log Z \rangle_{\mathbf{x}, \mathcal{G}} \quad (7)$$

$$Z = \int d\mathbf{f} \exp \left(-\frac{1}{2} \mathbf{f}^T \mathbf{C}^{-1} \mathbf{f} - \frac{1}{2\sigma^2} \sum_{i=1}^V \gamma_i f_i^2 - \frac{\lambda}{2} \mathbf{f}^T \mathbf{f} \right). \quad (8)$$

To bring this into a graphical model form we need to untangle the relationship between function values at different vertices arising from the prior. We first rewrite the prior term as an integral over its Fourier transform in order to eliminate the inverse of the covariance function. Carrying out the remaining, now factorised, integral over the f_i we are left with

$$Z = |\mathbf{S}|^{1/2} \int d\mathbf{h} \exp \left(-\frac{1}{2} \mathbf{h}^T \mathbf{C} \mathbf{h} - \frac{1}{2} \mathbf{h}^T \mathbf{S} \mathbf{h} \right) \quad (9)$$

where $\mathbf{S} = \text{diag}(1/(\frac{\gamma_1}{\sigma^2} + \lambda), \dots, 1/(\frac{\gamma_N}{\sigma^2} + \lambda))$ and we have dropped constant factors that do not depend on λ . If $p = 1$ we would now have the required graphical model form. For larger p , however, the first term in (9) still relates more than nearest neighbour vertices. We can make headway in dealing with the complicated interactions introduced by $\mathbf{C}$ by rewriting (4) in terms of a binomial expansion,

$$\mathbf{C} = \sum_{q=0}^p \binom{p}{q} (a^{-1})^q (1 - a^{-1})^{p-q} \mathbf{K}^{-1/2} (\mathbf{D}^{-1/2} \mathbf{A} \mathbf{D}^{-1/2})^q \mathbf{K}^{-1/2}. \quad (10)$$

We can now introduce $\mathbf{h}^q = (\mathbf{K}^{1/2} \mathbf{D}^{-1/2} \mathbf{A} \mathbf{D}^{-1/2} \mathbf{K}^{-1/2})^q \mathbf{h}$ into (9) recursively, by setting $\mathbf{h}^0 = \mathbf{h}$ and enforcing $\mathbf{h}^q = \mathbf{K}^{1/2} \mathbf{D}^{-1/2} \mathbf{A} \mathbf{D}^{-1/2} \mathbf{K}^{-1/2} \mathbf{h}^{q-1}$ for $q = 1, \dots, p$ using a Fourier transformed delta function. Our partition function then becomes

$$Z = |\mathbf{S}|^{1/2} \int \prod_{q=0}^p d\mathbf{h}^q \prod_{q=1}^p d\hat{\mathbf{h}}^q \exp \left(-\frac{1}{2} \sum_{q=0}^p c_q (\mathbf{h}^0)^T \mathbf{K}^{-1} \mathbf{h}^q - \frac{1}{2} (\mathbf{h}^0)^T \mathbf{S} \mathbf{h}^0 \right. \\ \left. + i \sum_{q=1}^p (\hat{\mathbf{h}}^q)^T \mathbf{h}^q - i \sum_{q=1}^p (\hat{\mathbf{h}}^q)^T \mathbf{K}^{1/2} \mathbf{D}^{-1/2} \mathbf{A} \mathbf{D}^{-1/2} \mathbf{K}^{-1/2} \mathbf{h}^{q-1} \right) \quad (11)$$

with $c_q = \binom{p}{q}(a^{-1})^q(1-a^{-1})^{p-q}$ and where we have again dropped λ -independent factors. We now have the desired form for Z . Rescaling variables in (11) to $(h^*)_i^q = h_i^q d_i^{-1/2} \kappa_i^{-1/2}$ and $(\hat{h}^*)_i^q = \hat{h}_i^q d_i^{-1/2} \kappa_i^{1/2}$ and rewriting explicitly in terms of vertex and interaction terms we have, after dropping the asterisks again,

$$Z = \int d\tilde{\mathbf{h}} \prod_{i \in \mathcal{V}} \exp\left(-\mathcal{H}(\tilde{\mathbf{h}}_i, d_i, \kappa_i, \gamma_i)\right) \prod_{(i,j) \in \mathcal{E}} \exp\left[-\mathcal{J}(\tilde{\mathbf{h}}_i, \tilde{\mathbf{h}}_j)\right] \quad (12)$$

with

$$\mathcal{H}(\tilde{\mathbf{h}}, d, \kappa, \gamma) = \frac{d}{2} \sum_{q=0}^p c_q h^0 h^q + \frac{\kappa d (h^0)^2}{2(\gamma/\sigma^2 + \lambda)} - i d \sum_{q=1}^p \hat{h}^q h^q - \frac{1}{2} \log\left(\frac{\kappa}{\gamma/\sigma^2 + \lambda}\right) \quad (13)$$

$$\mathcal{J}(\tilde{\mathbf{h}}, \tilde{\mathbf{h}}') = i \sum_{q=1}^p \left(\hat{h}^q (h')^{q-1} + (\hat{h}')^q h^{q-1} \right) \quad (14)$$

and $\tilde{\mathbf{h}} = (h^0, \dots, h^p, \hat{h}^1, \dots, \hat{h}^p)^\top$. Equation (12) is now in the form of a (complex-valued) Gaussian graphical model on a graph with local fields and interactions only between nearest neighbour pairs.

We can now proceed in the standard way using replicas. Since $\langle \log Z \rangle_{\mathbf{x}, \mathcal{G}}$ is hard to calculate we use the replica trick, $\langle \log Z \rangle_{\mathbf{x}, \mathcal{G}} = \lim_{n \rightarrow 0} \frac{1}{n} \log \langle Z^n \rangle_{\mathbf{x}, \mathcal{G}}$, to bring the averages inside the logarithm. We calculate $\langle Z^n \rangle_{\mathbf{x}, \mathcal{G}}$ for integer n and perform an analytic continuation to $n \rightarrow 0$ at the end.

Even after introducing replicas, the average of the replicated partition function over inputs (and, here, graphs) may be analytically intractable, depending on what stage in the calculation averages are carried out. It is here that our method and earlier approximations in continuous spaces [8, 12] differ: in the latter approaches, because the graph structure could not be exploited, the average over inputs $\mathbf{x}$ has to be kept in general form. To proceed, a Gaussian variational approximation was used in [12]. One can show [26] that for the case of GPs defined on graphs as considered here, this variational approximation of the input average in terms of two moments only ignores some of fluctuations in the number of examples γ_i seen at each vertex. In this paper we will take a different approach. We do not attempt to carry out the input average from the start; instead we perform the graph average and decouple vertices by introducing replica densities. The input average can then be kept without approximation right until the final saddle point equations. That this is possible is based on the following fact: if N training inputs i_μ are chosen randomly from, say, a uniform distribution over vertices, then for a large graph ($V \rightarrow \infty$) this is equivalent to each γ_i being independently sampled from a Poisson distribution with mean ν where $\nu = N/V$. We can therefore carry out the input average independently over the different vertices, without approximating the distribution of the γ_i . This will result in predictions for the learning curve that are exact across the entire range from small to large ν . For simplicity we restrict ourselves here to the case of a uniform input distribution, though all results generalise straightforwardly to the case where the input distribution is ω_i/V , with the ω_i weights of order unity that sum to V .

Finally in order to perform the average over the graph ensemble, we consider ensembles consisting of all graphs with a fixed but arbitrary degree distribution $p(d)$. To ensure that the graphs are sparsely connected and therefore locally tree-like, we assume that the mean degree $\bar{d}$ is finite, i.e. does not grow with V . With these assumptions we are now able to apply the replica method to (12).

3. Replica analysis

Our method for calculating (7) from the average of $\log Z$ as defined in (12) for $V \rightarrow \infty$ follows the approach of [25]. We begin by briefly considering the graph average for the class of ensembles of graphs assumed in this paper.

For a fixed degree sequence $\{d_1, \dots, d_V\}$, a uniform distribution over all graphs G with the correct degree sequence is given by

$$P(G|\{d_1 \dots d_V\}) = \frac{1}{\mathcal{N}} \prod_{(i,j)} p(a_{ij}) \delta_{a_{ij}, a_{ji}} \prod_i \delta_{d_i, \sum_{j \neq i} a_{ij}} \quad (15)$$

$$p(a_{ij}) = \frac{\bar{d}}{V} \delta_{a_{ij}, 1} + \left(1 - \frac{\bar{d}}{V}\right) \delta_{a_{ij}, 0}$$

with $\mathcal{N}$ defined to be the normaliser of $P(G|\{d_1 \dots d_V\})$. All the results that we are interested in are invariant under a relabelling of the graph vertices, and will therefore depend only on the degree distribution $p(d) = \frac{1}{V} \sum_i \delta_{d_i, d}$. The mean degree is $\bar{d} = \frac{1}{V} \sum_i d_i = \sum_d p(d) d$. The factors $p(a_{ij})$ above do not affect $P(G|\{d_1 \dots d_V\})$ as the number of non-zero a_{ij} is fixed by the degree constraints, but simplify the calculation.

We split our replica analysis of the learning curve into two sections corresponding to two different ways of normalising the covariance kernel, as specified by the normalisation coefficients κ_i . In section 3.1, we consider a *globally normalised kernel* where $\kappa_i = \kappa$, a constant equal to the average prior variance of the unnormalised kernel. This fixes the average of the prior variances at all vertices to unity. In section 3.2, we consider a *locally normalised kernel*, where κ_i is set equal to the local prior variance of vertex i of the unnormalised kernel: this forces all local prior variances to be exactly (rather than just on average) equal to unity.

3.1. Global normalisation

For a large ($V \rightarrow \infty$) graph, the normalisation by the average prior variance of the unnormalised kernel does not depend on the specific graph sampled. Thus we may solve (13) with an arbitrary constant $\kappa_i = \kappa$. In order to calculate the learning curve all that is then required is to set initially $\kappa = 1$, calculate the generalisation error at $\nu = 0$ and set κ equal to the result. The generalisation error from the globally normalised kernel can then be calculated with this κ for any required value of ν .

The learning curve calculation for global normalisation will follow essentially the method of [25], so we will keep explanations brief. Our derivation begins by raising (12)

to the power n , substituting $\kappa_i = \kappa$ and including the graph and input averages

$$\begin{aligned} \langle Z^n \rangle_{\mathbf{x}, \mathcal{G}} = & \left\langle \int \prod_{a=1}^n d\tilde{\mathbf{h}}^a \prod_{i \in \mathcal{V}} \exp \left(- \sum_{a=1}^n \mathcal{H}(\tilde{\mathbf{h}}_i^a, d_i, \kappa, \gamma_i) \right) \right. \\ & \times \left. \prod_{(i,j) \in \mathcal{E}} \exp \left(- \sum_{a=1}^n \mathcal{J}(\tilde{\mathbf{h}}_i^a, \tilde{\mathbf{h}}_j^a) \right) \right\rangle_{\{\gamma_i\}, \mathcal{G}}. \end{aligned} \quad (16)$$

We aim to rewrite (16) in terms of ‘replica densities’ so that we may calculate the graph average and then decouple different vertices. We define these replica densities as

$$\rho(\tilde{\mathbf{h}}^1, \dots, \tilde{\mathbf{h}}^n) = \frac{1}{V} \sum_i \prod_{a=1}^n \delta(\tilde{\mathbf{h}}^a - \tilde{\mathbf{h}}_i^a) e^{i\tilde{d}_i}, \quad (17)$$

and incorporate them into (16) with a functional delta using conjugate densities $\hat{\rho}$. Substituting (17) and the functional delta enforcement term into (16), performing the graph average and rearranging terms (see Appendix A.2.1, where $\hat{d}_i$ is also defined) we obtain

$$\langle Z^n \rangle_{\mathbf{x}, \mathcal{G}} = \frac{1}{\mathcal{N}} \int \mathcal{D}\rho \mathcal{D}\hat{\rho} \exp \left[V \left(\frac{\bar{d}}{2} (S_1[\rho] - 1) - iS_2[\rho, \hat{\rho}] + S_3[\hat{\rho}] \right) \right], \quad (18)$$

with

$$S_1[\rho] = \int \prod_{a=1}^n d\tilde{\mathbf{h}}^a d(\tilde{\mathbf{h}}^a)' \rho(\tilde{\mathbf{h}}^1, \dots, \tilde{\mathbf{h}}^n) \rho((\tilde{\mathbf{h}}^1)', \dots, (\tilde{\mathbf{h}}^n)') \exp \left[- \sum_{a=1}^n \mathcal{J}(\tilde{\mathbf{h}}^a, (\tilde{\mathbf{h}}^a)') \right] \quad (19a)$$

$$S_2[\rho, \hat{\rho}] = \int \prod_{a=1}^n d\tilde{\mathbf{h}}^a \rho(\tilde{\mathbf{h}}^1, \dots, \tilde{\mathbf{h}}^n) \hat{\rho}(\tilde{\mathbf{h}}^1, \dots, \tilde{\mathbf{h}}^n) \quad (19b)$$

$$S_3[\hat{\rho}] = \sum_d p(d) \log \left\langle \int \prod_{a=1}^n d\tilde{\mathbf{h}}^a \exp \left(- \sum_{a=1}^n \mathcal{H}(\tilde{\mathbf{h}}^a, d, \kappa, \gamma) \right) \frac{\left(i\hat{\rho}(\tilde{\mathbf{h}}^1, \dots, \tilde{\mathbf{h}}^n) \right)^d}{d!} \right\rangle_{\gamma}. \quad (19c)$$

We see that for $V \rightarrow \infty$, (18) will be dominated by its saddle point. To proceed we must make a specific assumption about the form of the replica densities at this saddle point. As in [25] we assume symmetric replicas, making the ansatz

$$\rho(\tilde{\mathbf{h}}^1, \dots, \tilde{\mathbf{h}}^n) = \int \mathcal{D}\psi \pi[\psi] \prod_{a=1}^n \frac{\exp \left(-\psi(\tilde{\mathbf{h}}^a) \right)}{Z[\psi]} \quad (20)$$

$$\hat{\rho}(\tilde{\mathbf{h}}^1, \dots, \tilde{\mathbf{h}}^n) = -i\bar{d} \int \mathcal{D}\hat{\psi} \hat{\pi}[\hat{\psi}] \prod_{a=1}^n \frac{\exp \left(-\hat{\psi}(\tilde{\mathbf{h}}^a) \right)}{Z[\hat{\psi}]}, \quad (21)$$

with the convention that

$$Z[f] = \int d\tilde{\mathbf{h}} \exp \left(-f(\tilde{\mathbf{h}}) \right). \quad (22)$$

This amounts to assuming each single replica function has a Gibbsian form. The average over π and $\hat{\pi}$ can be interpreted as representing, physically, an average over vertices i . We have included the prefactor $-i\bar{d}$ in (21) because this will ensure, in the end, that both π and $\hat{\pi}$ are normalised probability density functions.

We now substitute the ansatz (20) and (21) into (19a) to (19c), and expand in the number of replicas n up to $O(n)$. Terms involving λ first feature in the $O(n)$ term of $S_3[\hat{\rho}]$. Since the generalisation error (7) requires a derivative with respect to λ we must consider both the leading $O(n^0)$ and subleading $O(n)$ terms in calculating our saddle point contributions. We find that the leading $O(n^0)$ terms cancel with the graph normaliser, $\mathcal{N}$, and constrain π and $\hat{\pi}$ to be normalised distributions. The subleading saddle point equations together with these $O(n^0)$ normalisation constraints then give the self-consistency equation (see Appendix A.2.2)

$$\pi[\psi] = \sum_d \frac{p(d)d}{\bar{d}} \int \prod_{i=1}^{d-1} \mathcal{D}\psi^i \pi[\psi^i] \left\langle \delta(\psi - \Psi[\hat{\Psi}[\psi^1], \dots, \hat{\Psi}[\psi^{d-1}]]) \right\rangle_{\gamma}, \quad (23)$$

with

$$\Psi[\hat{\psi}^1, \dots, \hat{\psi}^{d-1}](\tilde{\mathbf{h}}) = \sum_{i=1}^{d-1} \hat{\psi}^i(\tilde{\mathbf{h}}) + \mathcal{H}(\tilde{\mathbf{h}}, d, \kappa, \gamma) \quad (24)$$

$$\hat{\Psi}[\psi](\tilde{\mathbf{h}}) = -\log \int d\tilde{\mathbf{h}}' \exp \left(-\psi(\tilde{\mathbf{h}}') - \mathcal{J}(\tilde{\mathbf{h}}, \tilde{\mathbf{h}}') \right), \quad (25)$$

Looking at the explicit form of $\mathcal{J}$ and $\mathcal{H}$, one sees that these equations are solved by ‘energy functions’ $\psi(\tilde{\mathbf{h}})$ that contain only quadratic terms in $\tilde{\mathbf{h}}$. This of course makes sense as we started from the partition function of a (complex) Gaussian graphical model. We can then write these functions as $\psi(\tilde{\mathbf{h}}) = \frac{1}{2} \tilde{\mathbf{h}}^T \mathbf{V}^{-1} \tilde{\mathbf{h}}$ in terms of their (complex valued) covariance matrices $\mathbf{V}$. In terms of the distribution of the $\mathbf{V}$, the self-consistency equation (23) becomes

$$\pi[\mathbf{V}] = \sum_d \frac{p(d)d}{\bar{d}} \int \prod_{i=1}^{d-1} d\mathbf{V}^i \pi[\mathbf{V}^i] \left\langle \delta(\mathbf{V} - (\mathbf{O} - \sum_{i=1}^{d-1} \mathbf{X} \mathbf{V}^i \mathbf{X})^{-1}) \right\rangle_{\gamma}, \quad (26)$$

with

$$\mathbf{O} = d \left(\begin{array}{ccc|ccc} c_0 + \frac{\kappa}{\gamma/\sigma^2 + \lambda} & \frac{1}{2}c_1 & \dots & \frac{1}{2}c_p & 0 & \dots & 0 \\ \frac{1}{2}c_1 & & & & -i & & \\ \vdots & & & & & \ddots & \\ \frac{1}{2}c_p & & & & & & -i \\ \hline 0 & -i & & & & & \\ \vdots & & \ddots & & & & \\ 0 & & & -i & \mathbf{0}_{p,p} & & \end{array} \right), \quad \mathbf{X} = \left(\begin{array}{ccc|ccc} & & & & i & & \\ & & & & & \ddots & \\ & \mathbf{0}_{p+1,p+1} & & & & & i \\ & & & & 0 & \dots & 0 \\ \hline i & & 0 & & & & \\ \vdots & & & & & & \\ \vdots & & & & & & \mathbf{0}_{p,p} \\ & & i & 0 & & & \end{array} \right).$$

At first sight (26) appears to have a singularity when $\gamma = 0$ and $\lambda \rightarrow 0$. Using Woodbury’s identity (see Appendix A.2.3) we can eliminate this apparent divergence and solve the self-consistency equation numerically using population dynamics [28]. This is an iterative technique where one creates a population of covariance matrices and for each iteration updates a random element of the population according to the delta function in (26). The update is calculated by sampling from the degree distribution $p(d)$ of local degrees, the Poisson distribution of the local number of examples ν and from

the distribution $\pi[\mathbf{V}^i]$ of “incoming” covariance matrices, the latter being approximated by uniform sampling from the current population.

Once a numerical solution for $\pi[\mathbf{V}]$ has been found, the generalisation error can be calculated from

$$\epsilon_g(\nu) = -\lim_{\lambda \rightarrow 0} \frac{\partial S_3^{O(n)}}{\partial \lambda} = \left\langle \sum_d p(d) \int \prod_{k=1}^d d\mathbf{V}_k \pi[\mathbf{V}_k] \frac{1}{\gamma/\sigma^2 + d\kappa \mathbf{e}_0^T \mathbf{M}_d^{-1} \mathbf{e}_0} \right\rangle_\gamma \quad (27)$$

where we have defined $S_3^{O(n)}$ as the $O(n)$ terms in the small- n expansion of S_3 (see Appendix A.2.2, also for the definition of $\mathbf{M}_d$), defined $\mathbf{e}_0 = (1, 0, \dots, 0)^T$ and again taken advantage of the Woodbury identity.

Equation (27) has a simple interpretation: once information from the rest of the graph has been folded in, any graph vertex has an ‘effective prior variance’ with precision $d\kappa(\mathbf{M}_d^{-1})_{00}$. This is then combined with the γ local examples to arrive at the final posterior variance at this vertex.

It is interesting to ask what the distribution of cavity covariances $\pi[\mathbf{V}]$ will be for different ν . Figure 3.1 (left) & (centre) show the log-distribution of V_{00} for random regular graphs (where each vertex has fixed equal degree) with degree $d = 3$. For $\nu = 0.0001$ the distribution appears to consist of delta peaks. This can be confirmed analytically by a Taylor expansion of (26) about $\nu = 0$. Each peak can be shown to be related to the variance of a vertex in a regular tree in which an example has been seen at increasing distances from the vertex. One would expect the peak with the highest amplitude to correspond to the variance of a vertex with an example seen at a distance p , because the number of vertices affected by an example grows with distance from example vertex. Further peaks are produced by examples at distances smaller than p , with height decreasing as distance and therefore number of affected vertices decreases. The V_{00} values also decrease, since the nearer to an example a vertex is, the more the local posterior variance is reduced. For larger ν more and more peaks are added until the distribution of V_{00} becomes effectively a continuous distribution, as seen for $\nu = 1$. Once ν becomes very large the GP has effectively learned the target function with very little remaining uncertainty, and so the distribution of posterior variances V_{00} becomes increasingly peaked near zero; this trend can be seen for $\nu = 10$.

Figure 3.1 (right) shows the equivalent plot for Erdős-Rényi random graphs (see section 4 for a description of this type of graph) with average degree 3. Since graph structure is now no longer uniform, one does not see a pattern of delta peaks for small ν as was the case for regular graphs. There are however visible peaks, around $V_{00} = 0$, $V_{00} = 1.15$ and $V_{00} = 1.4$, superimposed on a continuous distribution. This is from vertices with degree 1, 3 and 2 respectively. To see why, note that the cavity covariance matrices $\mathbf{V}$ can be interpreted as messages from a vertex that are sent to a neighbour, after incorporating the incoming messages from all other neighbours. Since vertices with degree 1 have no incoming messages, all messages sent from such vertices will be identical, resulting in a large peak in the distribution of V_{00} . The same reason also gives peaks from nodes with higher degree, as long as ν is small so that the majority

(Left) Normalised histograms of the top left entries V_{00} from a population of covariance matrices that solves the self-consistency condition (26), for random regular graphs with degree $d = 3$ and $\nu = 0.01$. (Centre) As left but for $\nu = 1$ and $\nu = 10$, the latter just visible as a narrow peak at the left edge of the distribution for $\nu = 1$. (Right) Analogue of left and centre figure combined for Erdős-Rényi random graphs with average connectivity 3.

of vertices has not yet seen an example (corresponding to $\gamma = 0$ in (26)). For example, the second peak in the figure is from vertices with degree 3 that receive two incoming messages from neighbours with degree 1. As these incoming messages are deterministic, so is the outgoing message if no local example has been seen. The third peak arises similarly from degree 2 vertices with an incoming message from a vertex with degree 1.

3.2. Local normalisation

Using the insight gained from the simpler globally normalised kernel, we now derive a prediction for the learning curve for the more complicated case of a locally normalised kernel. Here κ_i is equal to the prior variance at vertex i , as calculated from the unnormalised kernel. Although this may seem like a trivial change to the normalisation, it requires that properties of the quenched disorder are effectively defined via a second thermal average, making the calculation rather more complicated. The change from global to local normalisation can also be shown to cause significant changes to the GP prior over functions, and in turn to the learning curves [26].

We begin our calculation by including the site-dependent normalisation constants

κ_i in (13) via a delta enforcement term

$$Z = \int d\tilde{\mathbf{h}} d\boldsymbol{\kappa} \prod_{i \in \mathcal{V}} \exp\left(-\mathcal{H}(\tilde{\mathbf{h}}_i, d_i, \kappa_i, \gamma_i)\right) \prod_{(i,j) \in \mathcal{E}} \exp\left(-\mathcal{J}(\tilde{\mathbf{h}}_i, \tilde{\mathbf{h}}_j)\right) \\ \times \prod_{i \in \mathcal{V}} \delta\left(\kappa_i - \frac{1}{Z_{\text{aux}}} \int d\mathbf{f}_{\text{aux}} (f_{\text{aux},i})^2 \exp\left(-\frac{1}{2} \mathbf{f}_{\text{aux}}^T \mathbf{C}_0^{-1} \mathbf{f}_{\text{aux}}\right)\right). \quad (28)$$

Here Z_{aux} is defined to be the normaliser for an auxiliary GP $\mathbf{f}_{\text{aux}}$, and $\mathbf{C}_0 = (\mathbf{I} - a\mathbf{L})^p$ is the unnormalised kernel from (4).

Because the definitions of the κ_i depend on the entire graph in a non-local way, the partition function (28) no longer has the structure of a graphical model. Before we can apply the replica method, we need to bring it back into this form. This will require the introduction of an additional set of replicas, for the auxiliary GP.

Focussing on the κ_i -enforcement terms, we rewrite the delta functions in terms of their Fourier transform by introducing a conjugate variable $\hat{\kappa}_i$, and replace the integral over $\mathbf{f}_{\text{aux}}$ in the exponent with an empirical average over $L \rightarrow \infty$ replicas of $\mathbf{f}_{\text{aux}}$. With an element of foresight we also introduce $\lambda_{\text{aux}} \rightarrow 0$ so that later equations are well behaved for $\hat{\kappa}_i = 0$. The delta enforcement terms from (28) are then given by

$$\lim_{\substack{L \rightarrow \infty \\ \lambda_{\text{aux}} \rightarrow 0}} \int \prod_{i \in \mathcal{V}} \frac{d\hat{\kappa}_i}{2\pi} \prod_{l=1}^L \left(\frac{d\mathbf{f}_{\text{aux}}^l}{Z_{\text{aux}}} \right) \exp\left(\sum_{i \in \mathcal{V}} \left[i\hat{\kappa}_i \kappa_i - \frac{1}{2} \left(\frac{2i\hat{\kappa}_i}{L} + \lambda_{\text{aux}} \right) \sum_{l=1}^L (f_{\text{aux},i}^l)^2 \right]\right) \\ \times \exp\left(-\frac{1}{2} \sum_{l=1}^L (\mathbf{f}_{\text{aux}}^l)^T \mathbf{C}_0^{-1} \mathbf{f}_{\text{aux}}^l\right). \quad (29)$$

The non-local coupling via $\mathbf{C}_0^{-1}$ can be reduced to nearest neighbour interactions as for the original GP variables $\mathbf{f}$. In order to get (28) into the form of a graphical model it then remains to deal with the graph dependent Z_{aux} term. We bring Z_{aux} into the numerator by introducing $m - 1$ replicas of Z_{aux} and taking $m \rightarrow 0$ so that $Z_{\text{aux}}^{-1} = \lim_{m \rightarrow 0} Z_{\text{aux}}^{m-1}$. As is conventional in replica calculations, we then exchange the limits $m \rightarrow 0$ and $L \rightarrow \infty$, taking the latter first. The L -replica average over $(f_{\text{aux},i}^l)^2 \equiv (f_{\text{aux},i}^{l,1})^2$ can then be symmetrised to an Lm -replica average over the $(f_{\text{aux},i}^{l,b})^2$ with $b = 1, \dots, m$. This is because we have an infinite number mL of replicas at any fixed $m > 0$ so that both averages become non-fluctuating. At this point the only effect of m is via the total number of replicas mL , and to simplify the notation we can fix $m = 1$. At the end of the calculation of $\langle \log Z \rangle$ we then in principle have to replace L by mL and take $m \rightarrow 0$. However, as for the generalisation error we only need the λ -derivative, which does not directly depend on the auxiliary degrees of freedom, this will not be necessary.

With these simplifications, and after also rescaling $\hat{\kappa}_i$ by a factor of L for later

convenience, the delta function constraints for the κ_i take the form

$$\lim_{\substack{\lambda_{\text{aux}} \rightarrow 0 \\ L \rightarrow \infty}} \int \frac{d\hat{\kappa}_i L}{2\pi} \prod_{l=1}^L d\mathbf{f}_{\text{aux}}^l \exp \left(\sum_{i \in \mathcal{V}} \left[iL\hat{\kappa}_i \kappa_i - \frac{1}{2} (2i\hat{\kappa}_i + \lambda_{\text{aux}}) \sum_{l=1}^L (f_{\text{aux},i}^l)^2 \right] \right) \times \exp \left(-\frac{1}{2} \sum_{l=1}^L (\mathbf{f}_{\text{aux}}^l)^T \mathbf{C}_0^{-1} \mathbf{f}_{\text{aux}}^l \right). \quad (30)$$

Finally rewriting (30) using the same techniques as we did for Z in section 2, by Fourier transforming the covariance, integrating out the remaining terms, introducing $2p$ additional variables at each site, rescaling according to $(h^*)_{\text{aux},i}^q = h_{\text{aux},i}^q d_i^{-1/2}$ and $(\hat{h}^*)_{\text{aux},i}^q = \hat{h}_{\text{aux},i}^q d_i^{-1/2}$ and dropping the asterisks again, we arrive at the desired graphical model form from the partition function:

$$Z = \lim_{\substack{\lambda_{\text{aux}} \rightarrow 0 \\ L \rightarrow \infty}} \int d\tilde{\mathbf{h}} \frac{d\kappa d\hat{\kappa} L^V}{(2\pi)^V} \prod_{l=1}^L d\tilde{\mathbf{h}}_{\text{aux}}^l \prod_{(i,j) \in \mathcal{E}} \exp \left(-\mathcal{J}(\tilde{\mathbf{h}}_i, \tilde{\mathbf{h}}_j) - \sum_{l=1}^L \mathcal{J}(\tilde{\mathbf{h}}_{\text{aux},i}^l, \tilde{\mathbf{h}}_{\text{aux},j}^l) \right) \times \prod_{i \in \mathcal{V}} \exp \left(-\mathcal{H}(\tilde{\mathbf{h}}_i, d_i, \kappa_i, \gamma_i) + iL\kappa_i \hat{\kappa}_i - \sum_{l=1}^L \mathcal{H}_{\text{aux}}(\tilde{\mathbf{h}}_{\text{aux},i}^l, d_i, \hat{\kappa}_i) \right). \quad (31)$$

Here we have defined

$$\mathcal{H}_{\text{aux}}(\tilde{\mathbf{h}}_{\text{aux}}, d, \hat{\kappa}) = \frac{d}{2} \sum_{q=0}^p c_q h_{\text{aux}}^0 h_{\text{aux}}^q + \frac{d}{2} \frac{(h_{\text{aux}}^0)^2}{\lambda_{\text{aux}} + 2i\hat{\kappa}} - id \sum_{q=1}^p \hat{h}_{\text{aux}}^q h_{\text{aux}}^q - \frac{1}{2} \log \left(\frac{1}{\lambda_{\text{aux}} + 2i\hat{\kappa}} \right). \quad (32)$$

With (28) now in a form suitable for application of the replica method we proceed initially as we did in the case of global normalisation in section 3.1. We bring the graph and input average inside the logarithm using the replica trick at the cost of n additional replicas. The resulting average of Z^n reads

$$\langle Z^n \rangle_{\mathbf{x}, \mathcal{G}} = \lim_{L \rightarrow \infty} \left\langle \int \prod_{a=1}^n \left(d\tilde{\mathbf{h}}^a \frac{d\kappa^a d\hat{\kappa}^a L^V}{(2\pi)^V} \prod_{l=1}^L d\tilde{\mathbf{h}}_{\text{aux}}^{l,a} \right) \prod_{i \in \mathcal{V}} \exp \left(-\sum_{a=1}^n \mathcal{H}(\tilde{\mathbf{h}}_i^a, d_i, \kappa_i^a, \gamma_i) + iL \sum_{a=1}^n \kappa_i^a \hat{\kappa}_i^a - \sum_{a=1}^n \sum_{l=1}^L \mathcal{H}_{\text{aux}}(\tilde{\mathbf{h}}_{\text{aux},i}^{l,a}, d_i, \hat{\kappa}_i^a) \right) \times \prod_{(i,j) \in \mathcal{E}} \exp \left(-\sum_{a=1}^n \mathcal{J}(\tilde{\mathbf{h}}_i^a, \tilde{\mathbf{h}}_j^a) - \sum_{a=1}^n \sum_{l=1}^L \mathcal{J}(\tilde{\mathbf{h}}_{\text{aux},i}^{l,a}, \tilde{\mathbf{h}}_{\text{aux},j}^{l,a}) \right) \right\rangle_{D, \mathcal{G}}. \quad (33)$$

Similarly to the global case we introduce replica densities

$$\rho(\tilde{\mathbf{h}}^1, \dots, \tilde{\mathbf{h}}^n, \tilde{\mathbf{h}}_{\text{aux}}^{1,1}, \dots, \tilde{\mathbf{h}}_{\text{aux}}^{n,L}, \kappa^1, \dots, \kappa^n, \hat{\kappa}^1, \dots, \hat{\kappa}^n) = \frac{1}{V} \sum_i e^{i\hat{d}_i} \prod_{a=1}^n \delta(\tilde{\mathbf{h}}^a - \tilde{\mathbf{h}}_i^a) \delta(\kappa^a - \kappa_i^a) \delta(\hat{\kappa}^a - \hat{\kappa}_i^a) \times \prod_{a=1}^n \prod_{l=1}^L \delta(\tilde{\mathbf{h}}_{\text{aux}}^{l,a} - \tilde{\mathbf{h}}_{\text{aux},i}^{l,a}) \quad (34)$$

with enforcement via conjugate densities $\hat{\rho}$. We substitute the densities into (33) and perform the average over the graph ensemble to derive, using techniques similar to those for the global case (see Appendix A.2.1),

$$\langle Z^n \rangle_{\mathbf{x}, \mathcal{G}} = \frac{1}{\mathcal{N}} \int \mathcal{D}\rho \mathcal{D}\hat{\rho} \exp \left(V \left[\frac{\bar{d}}{2} (S_1[\rho] - 1) - i S_2[\rho, \hat{\rho}] + S_3[\hat{\rho}] \right] \right) \quad (35)$$

where

$$S_1[\rho] = \int \prod_{a=1}^n \left(d\tilde{\mathbf{h}}^a d(\tilde{\mathbf{h}}^a)' \frac{d\kappa^a d\hat{\kappa}^a L}{2\pi} \frac{d(\kappa^a)' d(\hat{\kappa}^a)' L}{2\pi} \prod_{l=1}^L d\tilde{\mathbf{h}}_{\text{aux}}^{l,a} d(\tilde{\mathbf{h}}_{\text{aux}}^{l,a})' \right) \rho(\dots) \rho(\dots') \quad (36a)$$

$$\times \exp \left(- \sum_{a=1}^n \mathcal{J}(\tilde{\mathbf{h}}^a, (\tilde{\mathbf{h}}^a)') - \sum_{a=1}^n \sum_{l=1}^L \mathcal{J}(\tilde{\mathbf{h}}_{\text{aux}}^{l,a}, (\tilde{\mathbf{h}}_{\text{aux}}^{l,a})') \right)$$

$$S_2[\rho, \hat{\rho}] = \int \prod_{a=1}^n \left(d\tilde{\mathbf{h}}^a \frac{d\kappa^a d\hat{\kappa}^a L}{2\pi} \prod_{l=1}^L d\tilde{\mathbf{h}}_{\text{aux}}^{l,a} \right) \rho(\dots) \hat{\rho}(\dots) \quad (36b)$$

$$S_3[\hat{\rho}] = \sum_d p(d) \log \left\langle \int \prod_{a=1}^n \left(d\tilde{\mathbf{h}}^a \frac{d\kappa^a d\hat{\kappa}^a L}{2\pi} \prod_{l=1}^L d\tilde{\mathbf{h}}_{\text{aux}}^{l,a} \right) \exp \left(- \sum_{a=1}^n \mathcal{H}(\tilde{\mathbf{h}}^a, d, \kappa^a, \gamma) \right. \right. \quad (36c)$$

$$\left. \left. + iL \sum_{a=1}^n \kappa^a \hat{\kappa}^a - \sum_{a=1}^n \sum_{l=1}^L \mathcal{H}_{\text{aux}}(\tilde{\mathbf{h}}_{\text{aux}}^{l,a}, d, \hat{\kappa}^a) \right) \frac{(i\hat{\rho}(\dots))^d}{d!} \right\rangle_{\gamma}.$$

We have not written the limits $\lambda_{\text{aux}} \rightarrow 0$ and $L \rightarrow \infty$ explicitly here.

As before, the expression (35) for the average of the replicated partition function will be dominated by its saddle point for large V . We assume that this saddle point has a replica symmetric form and set

$$\rho(\dots) = \int \mathcal{D}\psi \mathcal{D}\psi_{\kappa} \mathcal{D}\psi_{\text{aux}} \pi[\psi, \psi_{\kappa}, \psi_{\text{aux}}] \quad (37)$$

$$\times \prod_{a=1}^n \frac{\exp \left(-\psi(\tilde{\mathbf{h}}^a) - \psi_{\kappa}(\kappa^a, \hat{\kappa}^a) \right)}{Z[\psi] Z[\psi_{\kappa}]} \prod_{l=1}^L \frac{\exp \left(-\psi_{\text{aux}}(\tilde{\mathbf{h}}_{\text{aux}}^{l,a}) \right)}{Z[\psi_{\text{aux}}]}$$

$$\hat{\rho}(\dots) = -i\bar{d} \int \mathcal{D}\hat{\psi} \mathcal{D}\hat{\psi}_{\kappa} \mathcal{D}\hat{\psi}_{\text{aux}} \hat{\pi}[\hat{\psi}, \hat{\psi}_{\kappa}, \hat{\psi}_{\text{aux}}] \quad (38)$$

$$\times \prod_{a=1}^n \frac{\exp \left(-\hat{\psi}(\tilde{\mathbf{h}}^a) - \hat{\psi}_{\kappa}(\kappa^a, \hat{\kappa}^a) \right)}{Z[\hat{\psi}] Z[\hat{\psi}_{\kappa}]} \prod_{l=1}^L \frac{\exp \left(-\hat{\psi}_{\text{aux}}(\tilde{\mathbf{h}}_{\text{aux}}^{l,a}) \right)}{Z[\hat{\psi}_{\text{aux}}]}.$$

Any dependences between $\tilde{\mathbf{h}}$, $\tilde{\mathbf{h}}_{\text{aux}}$, κ and $\hat{\kappa}$ are encoded in the distributions π and $\hat{\pi}$. Given that the latter have the interpretation of distributions across vertices, one would expect that $\psi_{\kappa}(\kappa^a, \hat{\kappa}^a)$ ends up constraining κ_a to a definite value, with π then expressing how the local distributions of $\tilde{\mathbf{h}}^a$ and $\tilde{\mathbf{h}}_{\text{aux}}^{l,a}$ are correlated with this value of κ_a . This is indeed what we will find.

Substituting (37) and (38) into (36a) to (36c), we can write each of the exponent functions as expansions in n and nL , setting $S_i = S_i^{O(1)} + nS_i^{O(n)} + nLS_i^{O(nL)}$ up to linear order in n . As before, and as is standard in replica calculations, the subleading $O(n)$ terms are required in order to calculate the generalisation error. The novel feature

of the present calculation is the presence of the $O(nL)$ term arising from the auxiliary replicas.

The expansions for S_1 and S_2 are calculated in a similar manner to the global case and yield

$$S_1^{O(nL)}[\rho] = \int \mathcal{D}\psi \mathcal{D}\psi_\kappa \mathcal{D}\psi_{\text{aux}} \pi[\psi, \psi_\kappa, \psi_{\text{aux}}] \int \mathcal{D}\psi' \mathcal{D}\psi'_\kappa \mathcal{D}\psi'_{\text{aux}} \pi[\psi', \psi'_\kappa, \psi'_{\text{aux}}] \log \int d\tilde{\mathbf{h}}_{\text{aux}} d\tilde{\mathbf{h}}'_{\text{aux}} \frac{\exp\left(-\mathcal{J}(\tilde{\mathbf{h}}_{\text{aux}}, \tilde{\mathbf{h}}'_{\text{aux}}) - \psi_{\text{aux}}(\tilde{\mathbf{h}}_{\text{aux}}) - \psi'_{\text{aux}}(\tilde{\mathbf{h}}'_{\text{aux}})\right)}{Z[\psi_{\text{aux}}]Z[\psi'_{\text{aux}}]} \quad (39)$$

$$S_2^{O(nL)}[\rho, \hat{\rho}] = -i\bar{d} \int \mathcal{D}\psi \mathcal{D}\psi_\kappa \mathcal{D}\psi_{\text{aux}} \pi[\psi, \psi_\kappa, \psi_{\text{aux}}] \int \mathcal{D}\hat{\psi} \mathcal{D}\hat{\psi}_\kappa \mathcal{D}\hat{\psi}_{\text{aux}} \hat{\pi}[\hat{\psi}, \hat{\psi}_\kappa, \hat{\psi}_{\text{aux}}] \times \log \int d\tilde{\mathbf{h}}_{\text{aux}} \frac{\exp\left(-\psi_{\text{aux}}(\tilde{\mathbf{h}}_{\text{aux}}) - \hat{\psi}_{\text{aux}}(\tilde{\mathbf{h}}_{\text{aux}})\right)}{Z[\psi_{\text{aux}}]Z[\hat{\psi}_{\text{aux}}]} \quad (40)$$

for $O(nL)$, while for $O(n)$

$$S_1^{O(n)}[\rho] = \int \mathcal{D}\psi \mathcal{D}\psi_\kappa \mathcal{D}\psi_{\text{aux}} \pi[\psi, \psi_\kappa, \psi_{\text{aux}}] \int \mathcal{D}\psi' \mathcal{D}\psi'_\kappa \mathcal{D}\psi'_{\text{aux}} \pi[\psi', \psi'_\kappa, \psi'_{\text{aux}}] \times \log \left[\int d\tilde{\mathbf{h}} d\tilde{\mathbf{h}}' \frac{\exp\left(-\mathcal{J}(\tilde{\mathbf{h}}, \tilde{\mathbf{h}}') - \psi(\tilde{\mathbf{h}}) - \psi'(\tilde{\mathbf{h}}')\right)}{Z[\psi]Z[\psi']} \right. \\ \left. \times \int d\kappa d\hat{\kappa} d\kappa' d\hat{\kappa}' \frac{\exp\left(-\psi_\kappa(\kappa, \hat{\kappa}) - \psi'_\kappa(\kappa', \hat{\kappa}')\right)}{Z[\psi_\kappa]Z[\psi'_\kappa]} \right] \quad (41)$$

$$S_2^{O(n)}[\rho, \hat{\rho}] = -i\bar{d} \int \mathcal{D}\psi \mathcal{D}\psi_\kappa \mathcal{D}\psi_{\text{aux}} \pi[\psi, \psi_\kappa, \psi_{\text{aux}}] \int \mathcal{D}\hat{\psi} \mathcal{D}\hat{\psi}_\kappa \mathcal{D}\hat{\psi}_{\text{aux}} \hat{\pi}[\hat{\psi}, \hat{\psi}_\kappa, \hat{\psi}_{\text{aux}}] \times \log \int d\tilde{\mathbf{h}} d\kappa d\hat{\kappa} \frac{\exp\left(-\psi(\tilde{\mathbf{h}}) - \hat{\psi}(\tilde{\mathbf{h}}) - \psi_\kappa(\kappa, \hat{\kappa}) - \hat{\psi}_\kappa(\kappa, \hat{\kappa})\right)}{Z[\psi]Z[\hat{\psi}]Z[\psi_\kappa]Z[\hat{\psi}_\kappa]}. \quad (42)$$

The expansion for S_3 , on the other hand, is more complicated (see Appendix A.3.1). We extract $O(1)$ terms using the same technique as for the globally normalised kernel, leaving a logarithm containing both $O(n)$ and $O(nL)$ terms. Collecting the $\exp(iL\hat{\kappa}\kappa)$ term and the integral over $\tilde{\mathbf{h}}_{\text{aux}}$ we can rewrite the integrals over κ and $\hat{\kappa}$ in a form that can be evaluated by a saddle point method for large L . The saddle point equations fix $\hat{\kappa} = 0$ and $\kappa = 1/\lambda_{\text{aux}} - dv[\hat{\psi}_{\text{aux}}^1, \dots, \hat{\psi}_{\text{aux}}^d]/\lambda_{\text{aux}}^2$ in S_3 with

$$v[\hat{\psi}_{\text{aux}}^1, \dots, \hat{\psi}_{\text{aux}}^d] = \frac{\int d\tilde{\mathbf{h}}_{\text{aux}} (h_{\text{aux}}^0)^2 \exp\left(-\mathcal{H}_{\text{aux}}(\tilde{\mathbf{h}}_{\text{aux}}, d, 0) - \sum_{i=1}^d \hat{\psi}_{\text{aux}}^i(\tilde{\mathbf{h}}_{\text{aux}})\right)}{\int d\tilde{\mathbf{h}}_{\text{aux}} \exp\left(-\mathcal{H}_{\text{aux}}(\tilde{\mathbf{h}}_{\text{aux}}, d, 0) - \sum_{i=1}^d \hat{\psi}_{\text{aux}}^i(\tilde{\mathbf{h}}_{\text{aux}})\right)}. \quad (43)$$

With κ and $\hat{\kappa}$ determined by the large L -limit in this way, breaking $S_3[\hat{\rho}]$ up into $O(n)$ and $O(nL)$ terms becomes trivial and gives

$$S_3^{O(nL)}[\hat{\rho}] = \sum_d p(d) \int \prod_{i=1}^d \mathcal{D}\hat{\psi}^i \mathcal{D}\hat{\psi}_\kappa^i \mathcal{D}\hat{\psi}_{\text{aux}}^i \hat{\pi}[\hat{\psi}^i, \hat{\psi}_\kappa^i, \hat{\psi}_{\text{aux}}^i] \times \log \int d\tilde{\mathbf{h}}_{\text{aux}} \frac{\exp\left(-\mathcal{H}_{\text{aux}}(\tilde{\mathbf{h}}_{\text{aux}}, d, 0) - \sum_{i=1}^d \hat{\psi}_{\text{aux}}^i(\tilde{\mathbf{h}}_{\text{aux}})\right)}{\prod_{i=1}^d Z[\hat{\psi}_{\text{aux}}^i]} \quad (44)$$

$$\begin{aligned}
S_3^{O(n)}[\hat{\rho}] = \sum_d p(d) \left\langle \int \prod_{i=1}^d \mathcal{D}\hat{\psi}^i \mathcal{D}\hat{\psi}_\kappa^i \mathcal{D}\hat{\psi}_{\text{aux}}^i \hat{\pi}[\hat{\psi}^i, \hat{\psi}_\kappa^i, \hat{\psi}_{\text{aux}}^i] \right. \\
\times \log \left[\int d\tilde{\mathbf{h}} \frac{\exp\left(-\sum_{i=1}^d \hat{\psi}^i(\tilde{\mathbf{h}}) - \sum_{i=1}^d \hat{\psi}_\kappa^i\left(\frac{1}{\lambda_{\text{aux}}} - \frac{dv[\hat{\psi}_{\text{aux}}^1, \dots, \hat{\psi}_{\text{aux}}^d]}{\lambda_{\text{aux}}^2}, 0\right)\right)}{\prod_{i=1}^d Z[\hat{\psi}^i] Z[\hat{\psi}_\kappa^i]} \right. \\
\left. \left. \times \exp\left(-\mathcal{H}\left(\tilde{\mathbf{h}}, d, \frac{1}{\lambda_{\text{aux}}} - \frac{dv[\hat{\psi}_{\text{aux}}^1, \dots, \hat{\psi}_{\text{aux}}^d]}{\lambda_{\text{aux}}^2}, \gamma\right)\right) \right] \right\rangle_\gamma. \quad (45)
\end{aligned}$$

Here we have omitted a normalising factor that will be fixed to 1 by the leading order saddle point conditions. With S_1 , S_2 and S_3 in the desired expanded form we are now ready to find the generalisation error ϵ_g by a saddle point evaluation of (35). We find as before that the $O(1)$ saddle point conditions constrain π and $\hat{\pi}$ to be normalised densities. Enforcing these normalisation constraints using Lagrange multipliers in the higher order saddle point conditions, we are then able to derive self-consistency equations for π and $\hat{\pi}$.

The $O(nL)$ saddle point conditions give self-consistency conditions relating to the auxiliary variables. These have the same form as (23) for the original variables for the globally normalised kernel case, but with $\kappa = 1$ and $\gamma_i = 0$. Assuming once again a complex Gaussian solution with $\psi_{\text{aux}} = \frac{1}{2}\tilde{\mathbf{h}}_{\text{aux}}^T \mathbf{V}_{\text{aux}}^{-1} \tilde{\mathbf{h}}_{\text{aux}}$, we arrive at self-consistency equations that can be solved with population dynamics. These present an apparent singularity for $\lambda_{\text{aux}} \rightarrow 0$, but using the Woodbury identity this can be removed. Defining $\mathbf{M}_{\text{aux},d}$ in a similar manner to $\mathbf{M}_d$ but for the auxiliary variables we may rewrite the apparently singular combination that gives the saddle point value of κ (see section Appendix A.3.1) as

$$\frac{1}{\lambda_{\text{aux}}} - \frac{dv[\hat{\psi}_{\text{aux}}^1, \dots, \hat{\psi}_{\text{aux}}^d]}{\lambda_{\text{aux}}^2} = \frac{1}{\lambda_{\text{aux}} + d\mathbf{e}_0^T \mathbf{M}_{\text{aux},d}^{-1} \mathbf{e}_0}, \quad (46)$$

and then set $\lambda_{\text{aux}} = 0$.

Finally we consider the $O(n)$ terms for the non-auxiliary variables, which contain the λ -dependence that we need to find the generalisation error. The relevant saddle point conditions are

$$\begin{aligned}
\pi[\psi, \psi_\kappa | \mathbf{V}_{\text{aux}}] = \sum_d \frac{dp(d)}{d} \left\langle \int \prod_{i=1}^{d-1} \{ \mathcal{D}\psi^i \mathcal{D}\psi_\kappa^i d\mathbf{V}_{\text{aux}}^i \pi[\psi^i, \psi_\kappa^i | \mathbf{V}_{\text{aux}}^i] \pi[\mathbf{V}_{\text{aux}}^i] \} \right. \\
\times \delta\left(\psi - \Phi[\hat{\Phi}[\psi^1], \dots, \hat{\Phi}[\psi^{d-1}], \mathbf{V}_{\text{aux}}^1, \dots, \mathbf{V}_{\text{aux}}^{d-1}, \mathbf{V}_{\text{aux}}] \right. \\
\left. \left. \times \delta\left(\psi_\kappa - \Upsilon[\hat{\Upsilon}[\psi_\kappa^1], \dots, \hat{\Upsilon}[\psi_\kappa^{d-1}]]\right) \right) \right\rangle_\nu, \quad (47)
\end{aligned}$$

where

$$\begin{aligned}
\Phi[\hat{\psi}^1, \dots, \hat{\psi}^{d-1}, \mathbf{V}_{\text{aux}}^1, \dots, \mathbf{V}_{\text{aux}}^d](\tilde{\mathbf{h}}) = \sum_{i=1}^{d-1} \hat{\psi}^i(\tilde{\mathbf{h}}) + \mathcal{H}\left(\tilde{\mathbf{h}}, d, (d\mathbf{e}_0^T \mathbf{M}_{\text{aux},d}^{-1} \mathbf{e}_0)^{-1}, \gamma\right) \\
\hat{\Phi}[\psi](\tilde{\mathbf{h}}) = -\log \int d\tilde{\mathbf{h}}' \exp\left(-\mathcal{J}(\tilde{\mathbf{h}}, \tilde{\mathbf{h}}') - \psi(\tilde{\mathbf{h}}')\right) \quad (48)
\end{aligned}$$

$$\Upsilon[\hat{\psi}_\kappa^1, \dots, \hat{\psi}_\kappa^{d-1}](\kappa, \hat{\kappa}) = \sum_{i=1}^{d-1} \hat{\psi}_\kappa^i ((d\mathbf{e}_0^\top \mathbf{M}_{\text{aux},d}^{-1} \mathbf{e}_0)^{-1}, 0) \quad (49)$$

$$\hat{\Upsilon}[\psi_\kappa](\kappa, \hat{\kappa}) = -\log \int d\kappa' d\hat{\kappa}' \exp(-\psi_\kappa(\kappa', \hat{\kappa}')). \quad (50)$$

Taking advantage of (50) we can fix $\hat{\psi}_\kappa$ to be constant. Using this in (49) fixes ψ_κ to be κ and $\hat{\kappa}$ -independent also. With both ψ_κ and $\hat{\psi}_\kappa$ fixed we may remove them from π and $\hat{\pi}$. The remaining equation for the distribution of ψ can then be solved again using complex quadratic forms. Setting $\psi = \frac{1}{2} \tilde{\mathbf{h}}^\top \mathbf{V}^{-1} \tilde{\mathbf{h}}$ we have the self-consistency equation for the distribution of the $\mathbf{V}$,

$$\begin{aligned} \pi[\mathbf{V} | \mathbf{V}_{\text{aux}}^d] = \sum_d \frac{dp(d)}{d} \left\langle \int \prod_{i=1}^{d-1} \{d\mathbf{V}^i d\mathbf{V}_{\text{aux}}^i \pi[\mathbf{V}^i | \mathbf{V}_{\text{aux}}^i] \pi[\mathbf{V}_{\text{aux}}^i]\} \right. \\ \left. \times \delta \left(\mathbf{V} - (\tilde{\mathbf{O}} - \sum_{i=1}^{d-1} \mathbf{X} \mathbf{V}^i \mathbf{X})^{-1} \right) \right\rangle_\gamma \end{aligned} \quad (51)$$

with

$$\tilde{\mathbf{O}} = d \left(\begin{array}{ccc|ccc} c_0 + \frac{1}{d\mathbf{e}_0^\top \mathbf{M}_{\text{aux},d}^{-1} \mathbf{e}_0(\gamma/\sigma^2 + \lambda)} & \frac{1}{2}c_1 & \dots & \frac{1}{2}c_p & 0 & \dots & 0 \\ \frac{1}{2}c_1 & & & & -i & & \\ \vdots & & & & & \ddots & \\ \frac{1}{2}c_p & & & & & & -i \\ \hline 0 & & -i & & & & \\ \vdots & & & \ddots & & & \\ 0 & & & & -i & & \end{array} \right). \quad (52)$$

Once more we may take advantage of the Woodbury identity to deal with the apparent $\lambda \rightarrow 0$ singularity when $\gamma = 0$ (see Appendix A.2.3), and can then use population dynamics to numerically solve (51).

Finally, once we have obtained $\pi[\mathbf{V}_{\text{aux}}]$ and $\pi[\mathbf{V} | \mathbf{V}_{\text{aux}}]$, the generalisation error can be calculated by taking the λ derivative of $S_3^{O(n)}$. Utilising the Woodbury identity one last time so that we may take the $\lambda \rightarrow 0$ limit gives the expression

$$\epsilon_g = \left\langle \sum_d p(d) \int \prod_{i=1}^d d\mathbf{V}^i d\mathbf{V}_{\text{aux}}^i \pi[\mathbf{V}^i, \mathbf{V}_{\text{aux}}^i] \frac{1}{\gamma/\sigma^2 + (\mathbf{e}_0^\top \mathbf{M}_{\text{aux},d}^{-1} \mathbf{e}_0)^{-1} (\mathbf{e}_0^\top \mathbf{M}_d^{-1} \mathbf{e}_0)} \right\rangle_\gamma, \quad (53)$$

with $\mathbf{M}_d$ defined in a similar manner to the global case (see Appendix A.2.3). The interpretation is also similar: information from the rest of the graph provides an effective prior variance at any given node; the new element here is that this normalised by the prior variance in the absence of data, computed from the auxiliary variables.

4. Results

Using (26), (27), (51) and (53), we can now predict the learning curve for GP regression with a random walk covariance function on random graphs from ensembles specified

by arbitrary fixed degree distributions. We compare our replica-derived predictions for both globally and locally normalised kernels against a graph ensemble equivalent of the approximation presented in [8], and numerically simulated learning curves on graphs with 500 vertices, for a range of noise levels. In what follows, we will fix the hyperparameters a and p to be 2 and 10 respectively, but note that qualitatively similar results are obtained for other values of these hyperparameters.

In figure 1 we compare learning curve predictions for GP regression with a *globally* normalised kernel on two types of random graph ensembles. Figure 1 (left) shows results for the Erdős-Rényi [29] ensemble. Here each edge in the graph is present independently with some fixed probability of order $1/N$. This leads to a Poisson form for the degree distribution, $p_\lambda(d) = \lambda^d e^{-\lambda}/d!$; we choose the average degree λ to be 3. As can be seen the replica predictions greatly outperform the approximation from [8], especially in the mid section of the learning curve where fluctuations in the number of examples at each vertex have the greatest effect (see section 2 for discussion on why this is to be expected). In fact the replica theory accurately predicts the numerically simulated learning curve along its entire length. Figure 1 (right) similarly assesses our predictions for a graph ensemble with a power law distribution of degrees. This generalised random graph ensemble [30] is generated by a superposition of Poisson degree distributions with different means, $p(d) = \int d\lambda p(\lambda) p_\lambda(d)$. The distribution of the means λ is set to be a Pareto or power law distribution, $p(\lambda) = \alpha \lambda_m^\alpha / \lambda^{\alpha+1}$ for $\lambda \geq \lambda_m$ with the lower cut off λ_m set to be 2 and the exponent α chosen as 2.5. Once more we see that the replica method faithfully predicts the numerically simulated learning curves along their entire length. Comparison between the graph ensemble equivalent of [8] (not shown in figure 1 (right)) and numerically simulated learning curves again shows that this prediction fails to accurately predict the midsection of the learning curve.

Figure 2 (left & right) presents numerically simulated learning curves and theoretical predictions for a *locally* normalised kernel, again on Erdős-Rényi and generalised random graph ensembles with the same parameter settings as for the globally normalised kernel. Once more we see that our replica-derived learning curve prediction is accurate along the whole length of the curve. The graph equivalent of [8], however, again fails to accurately predict the mid-section of the leaning curve. We show in the inset of figure 2 (left) a more detailed plot of the somewhat unexpected shoulder that appears in the learning curves for the locally normalised kernel. This inset shows that the shoulder is due to the more realistic normalisation of disconnected vertices. Around the shoulder one can show that learning curves are dominated by mean-square errors of predictions on single disconnected vertices of the graph [26]. In contrast to the globally normalised case the variance at these vertices is fixed to 1 until an example is seen. Once on average one example has been seen at each disconnected vertex (i.e. around $\nu = 1$), the effect of these vertices becomes subdominant and the learning curves decay in a similar manner as for the globally normalised kernel. For a more detailed discussion of differences arising from the choice of global or local normalisation for the random walk kernel we refer to [26].

Figure 1. (Left) Learning curves for GP regression with a globally normalised kernel with $p = 10$ and $a = 2$ on Erdős-Rényi random graphs, for a range of noise levels. Solid lines with filled circles: numerically simulated learning curves for graphs of size $V = 500$, solid lines with triangles: replica predictions (see Section 3.1), dashed lines: The graph equivalent of [8]. (Right) Analogue of left figure for power law random graphs.

Figure 2. (Left) Learning curves for GP regression with a locally normalised kernel with $p = 10$ and $a = 2$ on Erdős-Rényi random graphs, for a range of noise levels. Solid lines with filled circles: numerically simulated learning curves for graphs of size $V = 500$, solid lines with triangles: replica predictions (see Section 3.2), dashed lines: The graph equivalent of [8]. (Left inset) Dashed lines show the contribution from disconnected single vertices to the learning curve (solid line with filled circles). (Right) Analogue of left figure for power law random graphs.

5. Conclusions

In this paper we focussed on predicting learning curves for GP regression with random walk kernels of functions defined on large random graphs. Using the replica method we derived accurate predictions for two normalisations of the kernel: global normalisation, where only the average of the prior variance across all vertices is fixed, and local normalisation, where the prior variance is uniform across all vertices. The random graph ensembles we considered are specified by a fixed but arbitrary degree distribution, making the results applicable to a broad range of graphs. We assume that the average degree is finite, which implies that the graphs are locally tree-like. This is, in the end, why the replica approach can give exact results for this problem in the limit of large graphs. For simplicity we also assumed that training inputs are drawn from a uniform distribution across all vertices, though the results generalise straightforwardly to more general input distributions.

We began in section 2 by rewriting the generalisation error (5) in terms of the partition function of a complex-valued graphical model (12). In section 3.1 we calculated the disorder average of the log partition function, for the case of a globally normalised kernel, applying a replica method similar to that of [25].

Section 3.2 then dealt with the case of a locally normalised kernel. Here the local normalisation constants are determined indirectly as the local prior variances of the unnormalised GP, and this non-local dependence on the quenched disorder (i.e. the graph structure) renders the analysis rather more complicated. We used a delta enforcement term to fix the local normalisers (equation (28)); rewriting this in its Fourier form and introducing an auxiliary set of replicas we were once again able to cast the relevant partition function in the form of a graphical model. The rest of the analysis then required an additional saddle point method *inside* the usual saddle calculation, to evaluate the ‘action’ governing the statistics of the replica densities.

Finally, in section 4 we compared our new predictions to an earlier approximation by Sollich [8], suitably extended to the graph case, and numerically simulated learning curves. Figure 1 for globally normalised kernels showed that our predictions are accurate along the whole length of the learning curve for both Erdős-Rényi and power law generalised random graph ensembles and for a range of noise levels. In figure 2 we showed similar results for the locally normalised case. We also briefly discussed the change in the shape of the learning curve that is caused by a change in normalisation from global to local.

In the future, it would be interesting to extend our approach to a larger class of graph ensembles, which embody graph structure beyond degree distributions. One could do this by applying the techniques in [31] where the replica method has been used to calculate eigenvalue spectra for graphs with topological constraints and ‘generalised’ degree distributions. The community structures studied in [31] could be further generalised by using the more general community graphs considered in [32], where the authors consider an adjacency matrix with block form and a sparse connectivity pattern

between the blocks.

An open problem is whether and how one could apply the methods from this paper to the significantly more complicated case of model mismatch, where teacher and student have different posterior distributions. In this case one would no longer be able to simplify the generalisation error to the posterior variance as was done in section 2, so that explicit averages over both teacher and student posteriors would need to be performed analytically. Preliminary work has shown that this would entail the introduction of an additional two local site variables and a second set of replicas. A novel extension of mismatch for the graph case would be to consider *graph* mismatch between student and teacher, where the underlying graph structure assumed by the student is a ‘corrupted’ version of the graph used by the teacher. Finally, it would be interesting to study how learning curves of real world data compare to the average case learning curves considered in this paper, for suitably chosen graph ensembles.

Appendix A. Details of replica analysis

Appendix A.1. Graph normaliser

In this section we derive the large V asymptotics of the graph ensemble normaliser $\mathcal{N}$ in (15). This is given as a sum over all possible graphs G ; i.e. over all adjacency matrices with elements $a_{ij} = a_{ji}$

$$\mathcal{N} = \sum_G \prod_{i < j} \left[\frac{\bar{d}}{V} \delta_{a_{ij},1} + \left(1 - \frac{\bar{d}}{V} \right) \delta_{a_{ij},0} \right] \prod_i \delta_{d_i, \sum_j a_{ij}} \quad (\text{A.1})$$

$$= \int_0^{2\pi} \prod_i \frac{d\hat{d}_i}{2\pi} e^{-i\hat{d}_i d_i} \prod_{i < j} \sum_{a_{ij} \in \{0,1\}} \left[\frac{\bar{d}}{V} \delta_{a_{ij},1} + \left(1 - \frac{\bar{d}}{V} \right) \delta_{a_{ij},0} \right] e^{ia_{ij}(\hat{d}_i + \hat{d}_j)} \quad (\text{A.2})$$

$$= \int_0^{2\pi} \prod_i \frac{d\hat{d}_i}{2\pi} e^{-i\hat{d}_i d_i} \prod_{i,j} \exp \left(\frac{\bar{d}}{2V} \left(e^{i(\hat{d}_i + \hat{d}_j)} - 1 \right) \right), \quad (\text{A.3})$$

where going from (A.2) to (A.3) we have assumed that V is large so that $\exp(\frac{x}{V}) \approx 1 + \frac{x}{V}$. Defining the density $\rho_0 = \frac{1}{V} \sum_i e^{i\hat{d}_i}$ with a conjugate enforcement term $\hat{\rho}_0$, (A.3) becomes,

$$\mathcal{N} = V \int d\rho_0 d\hat{\rho}_0 \exp \left(V \left[\frac{\bar{d}}{2} (\rho_0^2 - 1) - i\rho_0 \hat{\rho}_0 \right] \right) \prod_i \int_0^{2\pi} \frac{d\hat{d}_i}{2\pi} e^{-i\hat{d}_i d_i} e^{i\hat{\rho}_0 \sum_i \exp(i\hat{d}_i)}. \quad (\text{A.4})$$

Rewriting the final exponential in terms of its power series and performing the integration over $\hat{d}_i$ gives

$$\mathcal{N} = V \int d\rho_0 d\hat{\rho}_0 \exp \left(V \left[\frac{\bar{d}}{2} \{\rho_0^2 - 1\} - i\rho_0 \hat{\rho}_0 \right] \right) \prod_i \frac{(i\hat{\rho}_0)^{d_i}}{d_i!}. \quad (\text{A.5})$$

Defining the degree distribution $p(d) = (1/V) \sum_i \delta_{d_i,d}$ as usual and bringing the final term into the exponent of the first gives us a form amenable to saddle point evaluation:

$$\mathcal{N} = V \int d\rho_0 d\hat{\rho}_0 \exp \left(V \left[\frac{\bar{d}}{2} (\rho_0^2 - 1) - i\rho_0 \hat{\rho}_0 + \sum_d p(d) \log \frac{(i\hat{\rho}_0)^d}{d!} \right] \right). \quad (\text{A.6})$$

The saddle point of the exponent occurs when

$$0 = \bar{d}\rho_0 - i\hat{\rho}_0 \quad (\text{A.7})$$

$$0 = -i\rho_0 + \sum_d p(d) d \hat{\rho}_0^{-1} \quad (\text{A.8})$$

and solving gives $\rho_0 = 1$ and $\hat{\rho}_0 = -i\bar{d}$.

Appendix A.2. Global normalisation

We detail in this section some of derivations of the equations in section 3.1 related to the learning curve for globally normalised kernels.

Appendix A.2.1. Deriving equation (18) from (16): Performing the graph average as in Appendix A.1, (16) becomes,

$$\begin{aligned} \langle Z^n \rangle_{\mathbf{x}, \mathcal{G}} = & \left\langle \int_0^{2\pi} \prod_i \frac{d\hat{d}_i}{2\pi} \prod_{a=1}^n d\tilde{\mathbf{h}}^a \prod_i \exp \left(- \sum_{a=1}^n \mathcal{H}(\tilde{\mathbf{h}}_i^a, d_i, \kappa, \gamma_i) - i\hat{d}_i d_i \right) \right. \\ & \times \left. \prod_{i,j} \exp \left(\frac{\bar{d}}{2V} \left[\exp \left(- \sum_{a=1}^n \mathcal{J}(\tilde{\mathbf{h}}_i^a, \tilde{\mathbf{h}}_j^a) + i(\hat{d}_i + \hat{d}_j) \right) - 1 \right] \right) \right\rangle_{\mathbf{x}}. \end{aligned} \quad (\text{A.9})$$

Using the replica densities defined in (17) we see that the final product in (A.9) can be rewritten in terms of (19a) by moving the product over i, j into the exponent and realising that summing over all $\tilde{\mathbf{h}}_i^a$ and $\tilde{\mathbf{h}}_j^a$ is the same as integrating over the replica densities. This gives the term $\exp(\frac{V\bar{d}}{2}(S_1 - 1))$ in (18).

In order to use (17) in (16) we must introduce a delta enforcement term. S_2 , defined in (19b), is a direct consequence of including the functional delta term,

$$\begin{aligned} \delta \left(V\rho(\dots) - \sum_i \prod_{a=1}^n \delta(\tilde{\mathbf{h}}^a - \tilde{\mathbf{h}}_i^a) e^{i\hat{d}_i} \right) = \\ \int \mathcal{D}\hat{\rho} \exp \left(i \int \prod_a d\tilde{\mathbf{h}}^a \hat{\rho}(\dots) \left(\sum_i \prod_{a=1}^n \delta(\tilde{\mathbf{h}}^a - \tilde{\mathbf{h}}_i^a) e^{i\hat{d}_i} - V\rho(\dots) \right) \right). \end{aligned} \quad (\text{A.10})$$

Finally S_3 , defined in (19c), is derived from the first product in (A.9) with the remaining term from (A.10). These factors give

$$\left\langle \int_0^{2\pi} \frac{d\hat{\mathbf{d}}}{(2\pi)^V} \prod_{a=1}^n d\tilde{\mathbf{h}}^a \prod_i \exp \left(- \sum_{a=1}^n \mathcal{H}(\tilde{\mathbf{h}}_i^a, d_i, \kappa, \gamma_i) - i\hat{d}_i d_i + i\hat{\rho}(\dots)_i e^{i\hat{d}_i} \right) \right\rangle_{\mathbf{x}}, \quad (\text{A.11})$$

where $\hat{\rho}(\dots)_i = \hat{\rho}(\tilde{\mathbf{h}}_i^1, \dots, \tilde{\mathbf{h}}_i^n)$. Bringing the integration over $\tilde{\mathbf{h}}$ into the exponent by using a logarithm and performing the same procedure as in Appendix A.1, in going from (A.4) to (A.5), gives

$$\exp \left(\log \left\langle \int \prod_{a=1}^n d\tilde{\mathbf{h}}^a \prod_i \exp \left(- \sum_{a=1}^n \mathcal{H}(\tilde{\mathbf{h}}_i^a, d_i, \kappa, \gamma_i) \right) \frac{(i\hat{\rho}(\dots)_i)^{d_i}}{d_i!} \right\rangle_{\mathbf{x}} \right). \quad (\text{A.12})$$

Since we integrate over each site independently and also the data average separates into independent Poisson averages over the number of examples γ_i at each vertex, we can introduce $p(d) = 1/V \sum_i \delta_{d_i, d}$ and replace the integral over $\tilde{\mathbf{h}}_i^a$ with an integral over $\tilde{\mathbf{h}}^a$. This yields the term $\exp(VS_3)$ in (18).

Appendix A.2.2. Deriving equation (23) from (18): Substituting (20) & (21) into (19a) to (19c) we have

$$\begin{aligned} S_1[\rho] = & \int \mathcal{D}\psi \mathcal{D}\psi' \pi[\psi] \pi[\psi'] \int \prod_{a=1}^n d\tilde{\mathbf{h}}^a d(\tilde{\mathbf{h}}^a)' \\ & \prod_{a=1}^n \frac{\exp \left(-\psi(\tilde{\mathbf{h}}^a) - \psi'(\tilde{\mathbf{h}}^a)' \right)}{Z[\psi] Z[\psi']} \exp \left(-\mathcal{J}(\tilde{\mathbf{h}}^a, (\tilde{\mathbf{h}}^a)') \right) \end{aligned} \quad (\text{A.13})$$

$$S_2[\rho, \hat{\rho}] = -i\bar{d} \int \mathcal{D}\psi \mathcal{D}\hat{\psi} \pi[\psi] \hat{\pi}[\hat{\psi}] \int \prod_{a=1}^n d\tilde{\mathbf{h}}^a \prod_{a=1}^n \frac{\exp\left(-\psi(\tilde{\mathbf{h}}^a) - \hat{\psi}(\tilde{\mathbf{h}}^a)\right)}{Z[\psi]Z[\hat{\psi}]} \quad (\text{A.14})$$

$$S_3[\hat{\rho}] = \sum_d p(d) \log \left\langle \frac{\bar{d}^d}{d!} \int \prod_{i=1}^d \mathcal{D}\hat{\psi}^i \hat{\pi}[\hat{\psi}^i] \int \prod_{a=1}^n d\tilde{\mathbf{h}}^a \exp\left(-\sum_{a=1}^n \mathcal{H}(\tilde{\mathbf{h}}^a, d, \kappa, \gamma)\right) \prod_{i=1}^d \prod_{a=1}^n \frac{\exp\left(-\hat{\psi}^i(\tilde{\mathbf{h}}^a)\right)}{Z[\hat{\psi}^i]} \right\rangle_{\gamma}. \quad (\text{A.15})$$

We now expand to order n , using $x^n = 1 + n \log(x) + \dots$. This gives

$$S_1[\rho] = \int \mathcal{D}\psi \mathcal{D}\psi' \pi[\psi] \pi[\psi'] \left[1 + n \log \int d\tilde{\mathbf{h}} d\tilde{\mathbf{h}}' \frac{\exp\left(-\psi(\tilde{\mathbf{h}}) - \psi'(\tilde{\mathbf{h}}') - \mathcal{J}(\tilde{\mathbf{h}}, \tilde{\mathbf{h}}')\right)}{Z[\psi]Z[\psi']} \right] \quad (\text{A.16})$$

$$S_2[\rho, \hat{\rho}] = -i\bar{d} \int \mathcal{D}\psi \mathcal{D}\hat{\psi} \pi[\psi] \hat{\pi}[\hat{\psi}] \left[1 + n \log \int d\tilde{\mathbf{h}} \frac{\exp\left(-\psi(\tilde{\mathbf{h}}) - \hat{\psi}(\tilde{\mathbf{h}})\right)}{Z[\psi]Z[\hat{\psi}]} \right] \quad (\text{A.17})$$

$$S_3[\hat{\rho}] = \sum_d p(d) \log \left[\frac{\bar{d}^d \int \prod_{i=1}^d \mathcal{D}\hat{\psi}^i \hat{\pi}[\hat{\psi}^i]}{d!} \right] + n \sum_d p(d) \int \prod_{i=1}^d \mathcal{D}\hat{\psi}^i \hat{\pi}[\hat{\psi}^i] \left\langle \log \int d\tilde{\mathbf{h}} \exp\left(-\mathcal{H}(\tilde{\mathbf{h}}, d, \kappa, \gamma)\right) \times \prod_{i=1}^d \frac{\exp\left(-\hat{\psi}^i(\tilde{\mathbf{h}})\right)}{Z[\hat{\psi}^i]} \right\rangle_{\gamma} \left[\int \prod_{i=1}^d \mathcal{D}\hat{\psi}^i \hat{\pi}[\hat{\psi}^i] \right]^{-1}. \quad (\text{A.18})$$

The leading $O(1)$ contributions yield as saddle point conditions for π and $\hat{\pi}$ simply $\int \mathcal{D}\psi \pi[\psi] = 1$ and $\int \mathcal{D}\hat{\psi} \hat{\pi}[\hat{\psi}] = 1$. With these normalisation constraints inserted, the $O(1)$ terms take the same form as in Appendix A.1. Thus for $V \rightarrow \infty$ the $O(1)$ terms in the exponent of (18) will cancel, and we are left as expected with the λ -dependent subleading $O(n)$ terms. These lead to the saddle point equations for $\pi[\psi]$ and $\hat{\pi}[\hat{\psi}]$

$$\mu = \bar{d} \int \mathcal{D}\psi' \pi[\psi'] \log \int d\tilde{\mathbf{h}} d\tilde{\mathbf{h}}' \frac{\exp\left(-\psi(\tilde{\mathbf{h}}) - \psi'(\tilde{\mathbf{h}}') - \mathcal{J}(\tilde{\mathbf{h}}, \tilde{\mathbf{h}}')\right)}{Z[\psi]Z[\psi']} - \bar{d} \int \mathcal{D}\hat{\psi} \hat{\pi}[\hat{\psi}] \log \int d\tilde{\mathbf{h}} \frac{\exp\left(-\psi(\tilde{\mathbf{h}}) - \hat{\psi}(\tilde{\mathbf{h}})\right)}{Z[\psi]Z[\hat{\psi}]} \quad (\text{A.19})$$

$$\begin{aligned}
\hat{\mu} = \sum_d p(d)d \int \prod_{i=1}^{d-1} \mathcal{D}\hat{\psi}^i \hat{\pi}[\hat{\psi}^i] \\
\times \left\langle \log \int d\tilde{\mathbf{h}} \frac{\exp\left(-\mathcal{H}(\tilde{\mathbf{h}}, d, \kappa, \gamma) - \hat{\psi}(\tilde{\mathbf{h}}) - \sum_{i=1}^{d-1} \hat{\psi}^i(\tilde{\mathbf{h}})\right)}{Z[\hat{\psi}] \prod_{i=1}^d Z[\hat{\psi}^i]} \right\rangle_{\gamma} \\
- \bar{d} \int \mathcal{D}\psi \pi[\psi] \log \int d\tilde{\mathbf{h}} \frac{\exp\left(-\psi(\tilde{\mathbf{h}}) - \hat{\psi}(\tilde{\mathbf{h}})\right)}{Z[\psi] Z[\hat{\psi}]},
\end{aligned} \tag{A.20}$$

where the $O(1)$ constraints have been enforced with Lagrange multipliers μ and $\hat{\mu}$. Looking at (A.19), the $Z[\psi']$ and $Z[\hat{\psi}]$ factors give additive constants that can be absorbed, along with the factors of $\bar{d}$, into a redefinition of μ . Bearing in mind the definition (25) of $\hat{\Psi}$, the resulting equation has the form

$$\mu = \int \mathcal{D}\psi' \pi[\psi'] F(\psi, \hat{\Psi}[\psi']) - \int \mathcal{D}\hat{\psi} \hat{\pi}[\hat{\psi}] F(\psi, \hat{\psi}) \tag{A.21}$$

in which $F(\psi, \hat{\psi}) = \log \int d\tilde{\mathbf{h}} Z^{-1}[\psi] \exp\left(-\psi(\tilde{\mathbf{h}}) - \hat{\psi}(\tilde{\mathbf{h}})\right)$. As this equation must hold for arbitrary ψ , it follows that the distribution of $\hat{\psi}$ must equal the distribution of $\hat{\Psi}[\psi']$, hence

$$\hat{\pi}[\hat{\psi}] = \int \mathcal{D}\psi \pi[\psi] \delta(\hat{\psi} - \hat{\Psi}[\psi]) \tag{A.22}$$

(To be precise, $\hat{\psi}$ and $\hat{\Psi}[\psi']$ can differ by an arbitrary additive constant because $F(\psi, \hat{\psi} + \text{const}) = F(\psi, \hat{\psi}) + \text{const}$; we fix this constant to the most convenient value in writing (A.22).) Similarly one derives from (A.20) that

$$\pi[\psi] = \sum_d \frac{p(d)d}{\bar{d}} \left\langle \int \prod_{i=1}^{d-1} \mathcal{D}\hat{\psi}^i \hat{\pi}[\hat{\psi}^i] \delta(\psi - \Psi[\hat{\psi}^1, \dots, \hat{\psi}^{d-1}]) \right\rangle_{\gamma} \tag{A.23}$$

with Ψ defined in (24). Combining this with (A.22) gives rise to (23).

Appendix A.2.3. Woodbury derivations The apparent singularity in the update equations given by (26) can be eliminated by using the Woodbury identity for inverting matrices [33]. We may write

$$\left(\mathbf{e}_0 \frac{d\kappa}{\gamma/\sigma^2 + \lambda} \mathbf{e}_0^T + \mathbf{M}_{d-1} \right)^{-1} = \mathbf{M}_{d-1}^{-1} - \frac{\mathbf{M}_{d-1}^{-1} \mathbf{e}_0 \mathbf{e}_0^T \mathbf{M}_{d-1}^{-1}}{(\gamma/\sigma^2 + \lambda) / (d\kappa) + \mathbf{e}_0^T \mathbf{M}_{d-1}^{-1} \mathbf{e}_0} \tag{A.24}$$

where $\mathbf{M}_{d-1} = \mathbf{O} - \sum_{i=1}^{d-1} \mathbf{X} \mathbf{V}^i \mathbf{X} - \mathbf{e}_0 \frac{d\kappa}{\gamma/\sigma^2 + \lambda} \mathbf{e}_0^T$ contains only λ -independent terms. On the right hand side of (A.24) we can now take $\lambda \rightarrow 0$ without problems, even when $\gamma = 0$.

A similar method may be applied to arrive at (27). Direct differentiation with respect to λ of $S_3^{O(n)}$, defined as the coefficient multiplying n in (A.18) will result in the following expression for the generalisation error:

$$\epsilon_g = \lim_{\lambda \rightarrow 0} \sum_d p(d)d \left\langle \frac{1}{\gamma/\sigma^2 + \lambda} \left[1 - \frac{d\kappa}{\gamma/\sigma^2 + \lambda} \mathbf{e}_0^T (\mathbf{O} - \sum_{i=1}^d \mathbf{X} \mathbf{V}^i \mathbf{X})^{-1} \mathbf{e}_0 \right] \right\rangle_{\gamma}. \tag{A.25}$$

If we now define $\mathbf{M}_d$ in analogy to $\mathbf{M}_{d-1}$ above, but with the sum over i running from 1 to d , we can substitute the analogue of (A.24) into (A.25) and take $\lambda \rightarrow 0$ to arrive at (27).

Appendix A.3. Local normalisation

We detail in this section some of the derivations of equations in section 3.2 related to the locally normalised kernel case.

Appendix A.3.1. Deriving equations (44) & (45) from equation (36c): We proceed as we did for the globally normalised kernel, substituting (37) and (38) into (36c) and taking advantage of $x^n = 1 + n \log(x) + \dots$. After extracting the $O(1)$ terms we are left with

$$S_3 - S_3^{O(1)} = n \sum_d p(d) \int \prod_{i=1}^d \mathcal{D}\hat{\psi}^i \mathcal{D}\hat{\psi}_\kappa^i \mathcal{D}\hat{\psi}_{\text{aux}}^i \hat{\pi}[\hat{\psi}^i, \hat{\psi}_\kappa^i, \hat{\psi}_{\text{aux}}^i] \log \left(\int \frac{d\tilde{\mathbf{h}} d\kappa d\hat{\kappa} L}{2\pi} \right. \\ \left. \int \prod_{l=1}^L d\tilde{\mathbf{h}}_{\text{aux}}^l \exp \left(-\mathcal{H}(\tilde{\mathbf{h}}, d, \kappa, \gamma) + iL\kappa\hat{\kappa} - \sum_{l=1}^L \mathcal{H}_{\text{aux}}(\tilde{\mathbf{h}}_{\text{aux}}^l, d, \hat{\kappa}) \right) \right. \\ \left. \prod_{i=1}^d \frac{\exp \left(-\hat{\psi}^i(\tilde{\mathbf{h}}) - \hat{\psi}_\kappa^i(\kappa, \hat{\kappa}) - \sum_{l=1}^L \hat{\psi}_{\text{aux}}^i(\tilde{\mathbf{h}}_{\text{aux}}^l) \right)}{Z[\hat{\psi}^i] Z[\hat{\psi}_\kappa^i] \prod_{l=1}^L Z[\hat{\psi}_{\text{aux}}^i, l]} \right). \quad (\text{A.26})$$

Here we have omitted a normalising denominator that will be set to unity by the $O(1)$ saddle point constraints. Grouping together the $\kappa, \hat{\kappa}$ and $\tilde{\mathbf{h}}_{\text{aux}}$ terms we see we may rewrite (A.26) in the form

$$n \sum_d p(d) \int \prod_{i=1}^d \mathcal{D}\hat{\psi}^i \mathcal{D}\hat{\psi}_\kappa^i \mathcal{D}\hat{\psi}_{\text{aux}}^i \hat{\pi}[\hat{\psi}^i, \hat{\psi}_\kappa^i, \hat{\psi}_{\text{aux}}^i] \\ \log \int d\tilde{\mathbf{h}} \int \frac{d\kappa d\hat{\kappa} L}{2\pi} \zeta(\tilde{\mathbf{h}}, \kappa, \hat{\kappa}) \exp \left(L \log \int d\tilde{\mathbf{h}}_{\text{aux}} \xi(\tilde{\mathbf{h}}_{\text{aux}}, \kappa, \hat{\kappa}) \right) \quad (\text{A.27})$$

with

$$\zeta(\tilde{\mathbf{h}}, \kappa, \hat{\kappa}) = \frac{\exp \left(-\mathcal{H}(\tilde{\mathbf{h}}, d, \kappa, \gamma) - \sum_{i=1}^d \hat{\psi}^i(\tilde{\mathbf{h}}) - \sum_{i=1}^d \hat{\psi}_\kappa^i(\kappa, \hat{\kappa}) \right)}{\prod_{i=1}^d Z[\hat{\psi}^i] Z[\hat{\psi}_\kappa^i]} \quad (\text{A.28})$$

$$\xi(\tilde{\mathbf{h}}_{\text{aux}}, \kappa, \hat{\kappa}) = \frac{\exp \left(-\mathcal{H}_{\text{aux}}(\tilde{\mathbf{h}}_{\text{aux}}, d, \hat{\kappa}) + i\kappa\hat{\kappa} - \sum_{i=1}^d \hat{\psi}_{\text{aux}}^i(\tilde{\mathbf{h}}_{\text{aux}}) \right)}{\prod_{i=1}^d Z[\hat{\psi}_{\text{aux}}^i]}. \quad (\text{A.29})$$

For L large the integral over κ and $\hat{\kappa}$ will be dominated by its saddle point. The saddle point conditions are

$$0 = i\hat{\kappa} \quad (\text{A.30})$$

$$0 = \frac{\int d\tilde{\mathbf{h}}_{\text{aux}} [-i/(\lambda_{\text{aux}} + 2i\hat{\kappa}) + i\kappa + id(h_{\text{aux}}^0)^2/(\lambda_{\text{aux}} + 2i\hat{\kappa})^2] \exp \left(\xi(\tilde{\mathbf{h}}_{\text{aux}}, \kappa, \hat{\kappa}) \right)}{\int d\tilde{\mathbf{h}}_{\text{aux}} \exp \left(\xi(\tilde{\mathbf{h}}_{\text{aux}}, \kappa, \hat{\kappa}) \right)}. \quad (\text{A.31})$$

This gives us, using the functional $v[\dots]$ defined in (43)

$$\kappa = \frac{1}{\lambda_{\text{aux}}} - d \frac{v[\psi_{\text{aux}}^1, \dots, \psi_{\text{aux}}^d]}{\lambda_{\text{aux}}^2} \quad (\text{A.32})$$

$$\hat{\kappa} = 0. \quad (\text{A.33})$$

One subtlety here is that we need to make sure that the integral over κ and $\hat{\kappa}$ in (A.27) is evaluated accurately including $O(1)$ prefactors, because such contributions will feed into the $O(n)$ terms in the action. To obtain these prefactors one needs to expand the exponent of (A.27) to second order about the saddle point. Fortunately the relevant Hessian of $\log \left(\int d\tilde{\mathbf{h}}_{\text{aux}} \xi(\tilde{\mathbf{h}}_{\text{aux}}, \kappa, \hat{\kappa}) \right)$ has a constant determinant, and the factor from the fluctuation correction is simply $(2\pi/L)$. This just cancels the scaling factor in front of the integral over κ and $\hat{\kappa}$. In this way one obtains for the $O(nL)$ contribution to S_3 the saddle point value of the exponent in (A.27), leading to (44) in the main text, while the $O(n)$ contribution given in (45) comes from the prefactor $\int d\tilde{\mathbf{h}} \zeta(\tilde{\mathbf{h}}, \kappa, \hat{\kappa})$.
